

Probabilistic Robotics - Assignment 4

Nedko Savov - 11404345
Athanasios Roidis - 11413441

October 10, 2017

1 Task 1

Before we start, a code problem with the code in EKF.m is addressed. In case of a "mark" tag in the log file, the code adds a state entry $(x, y, \theta) = (0, 0, 0)$ to the list of states. This effectively resets the pose of the robot after the mark and prevents from continuous transition between two mark datasets. This is why we altered the code not to include this entry.

During the prediction stage, the task is to model the current position of the robot, after performing a movement. Since no planning for future movement is required, an odometry model can be used. An odometry model is practically proven to be more accurate than a velocity model in the general case. Therefore some modifications had to be made to the given code.

First and foremost, we had to change the way the data was loaded so that the control vector u had the following form:

$$u = \begin{bmatrix} \delta_{trans} \\ \delta_{rot1} \\ \delta_{rot2} \end{bmatrix} = \begin{bmatrix} \sqrt{d_x^2 + d_y^2} \\ \text{atan2}(d_y, d_x) - \mu_{t-1, \theta} \\ \mu_{t, \theta} - \mu_{t-1, \theta} - \delta_{rot1} \end{bmatrix}, \quad d = \begin{bmatrix} \mu_{t, x} - \mu_{t-1, x} \\ \mu_{t, y} - \mu_{t-1, y} \end{bmatrix}$$

when the robot is moving from $\mu_{t-1} = (\mu_{t-1, x}, \mu_{t-1, y}, \mu_{t-1, \theta})$ to $\mu_t = (\mu_{t, x}, \mu_{t, y}, \mu_{t, \theta})$.

The new motion function is:

$$\bar{\mu}_t = \mu_{t-1} + \begin{bmatrix} \delta_{trans} \cos(\delta_{rot1} + \mu_{t-1, \theta}) \\ \delta_{trans} \sin(\delta_{rot1} + \mu_{t-1, \theta}) \\ \delta_{rot1} + \delta_{rot2} \end{bmatrix}$$

The Jacobian of the motion function with respect to the robot pose is then given by:

$$G = \begin{bmatrix} 1 & 0 & -\delta_{trans} * \sin(\delta_{rot1} + \mu_{t, \theta}) \\ 0 & 1 & \delta_{trans} * \cos(\delta_{rot1} + \mu_{t, \theta}) \\ 0 & 0 & 1 \end{bmatrix};$$

The Jacobian of the motion function with respect to the motion is given by:

$$V = \begin{bmatrix} \cos(\delta_{rot1} + \mu_{t, \theta}) & -\delta_{trans} \sin(\delta_{rot1} + \mu_{t, \theta}) & 0 \\ \delta_{trans} * \sin(\delta_{rot1} + \mu_{t, \theta}) & \delta_{trans} * \cos(\delta_{rot1} + \mu_{t, \theta}) & 0 \\ 0 & 1 & 1 \end{bmatrix};$$

Since the correction step is not related to the motion model, it was left untouched, as it was given.

Finally, the Q (measurement noise covariance) and M (control vector noise covariance) matrices should also be defined according to the assignment. As stated, there is a noise of 15% on range measurements and 10° (to be converted to radians) on the bearing. This is incorporated in the Q matrix:

$$Q = \begin{bmatrix} 0.15 * \text{range}(t, l) & 0 \\ 0 & 10 * \text{Pi}/180 \end{bmatrix}$$

, where $range(t, l)$ is the distance measured to landmark l at time t . Dependency on time step requires the Q matrix to be now recalculated at each iteration over the measurements.

Since noise on the odometry data is not known, some experimentation needs to be done with the initialization of the M matrix.

The state at each time step is stored from the algorithm in history variables. We start with the default value $M = 0.15I$, given in the original implementation. The data of the first 8 marks in the full dataset is used. Using this smaller subset can be used to visualize the corrected trajectory between all the marks and also to make the task computationally feasible for the approaches discussed next. Fig. 2 shows the estimated trajectory in this case. Visibly, the new trajectory goes closer to the marks than the original trajectory constructed from the noisy odometry observations (in red). However, there may be a better choice for M and the noise is visibly affecting the estimated trajectory with the default value. This noise is also visible with the big uncertainties, note that the plotted ellipses cover 34% confidence interval (half a standard deviation) for visualization purposes. An attempt is made to find a better choice for M by using grid search. To do this, a metric of a better choice of M has to be chosen. A trajectory is better than another if the sum of the distances from the estimated positions at the marked time to the actual positions of the marks is smaller. It should be noted that in this metric large uncertainty is not being penalized. Therefore, the resulting model has to be analyzed for this. The choice of ranges for M to be done grid search one partly make up for this problem. As defined in the textbook:

$$M = \begin{bmatrix} \alpha_1 \delta_{trans} + \alpha_2 \delta_{rot1} + \alpha_3 \delta_{rot2} & 0 & 0 \\ 0 & \alpha_4 \delta_{trans} + \alpha_5 \delta_{rot1} + \alpha_6 \delta_{rot2} & 0 \\ 0 & 0 & \alpha_7 \delta_{trans} + \alpha_8 \delta_{rot1} + \alpha_9 \delta_{rot2} \end{bmatrix}$$

The grid search is done over the α_1 to α_9 variables. For each of them a value is chosen from an array of K values. Since the variables are too many, some of them already need to have predetermined values. After some experimentation with small K and earlier termination, it was determined that α_8 and α_9 are mostly zero. also α_3 tends to match α_6 . After making these assignments, there are 6 variables to do the grid search on. The possible choices for values of all the variables are selected to be $[0, 0.15, 0.3]$. Other combinations were tried as well, but these gave the optimal result. The largest values is 0.3, as it is reasonable to assume that the odometry metrics are not extremely noisy. The result was $\alpha = [\alpha_1, \alpha_2, \alpha_3, \alpha_4, \alpha_5, \alpha_6, \alpha_7, \alpha_8, \alpha_9] = [0.3, 0, 0, 0.3, 0, 0, 0.3, 0, 0]$ The estimation for the best found M is plotted on Fig. 1b. It can be seen that while passing closely to all the other landmarks, the fifth landmark is further away from the path. However, it is still within the confidence range of the estimated position. It is visible that the estimated path has the expected eight shape, which is in contrast with the measured odometry positions.

An attempt to do grid search on the u_{error} , where $M = u_{error}I$, was also made, which yielded a value, giving estimation with similar distance metric.

As for how M influences the model - the more the noise applied to the control vector, trajectory disturbances become more erratic. Biggest changes happen on sharper corners or larger velocities.

For comparison, on Fig. 1 are shown the estimated trajectories for the first three marks from the velocity (originally implemented) and the odometry model. The best found M found for the odometry model was used. For the velocity model, the last dimension of M is cut to fit the size of the control vector. Of course, there may be better parameters for the velocity model. However, the figure is to show the observed property of the odometry model to more easily preserve the shape of the odometry measurements even after distortion, done to consider the noise.

On Fig. 3 it is shown the estimated trajectory of the robot together with the uncertainty ellipses at equal distances. The green ellipses show the uncertainty of only using prediction (based on the fully updated covariance from the previous step) and the black ones - the same covariance after the correction step. For this choice of the best found M , the difference is very small, in some cases - barely visible. This is to be expected, as the calculated M is usually small, causing the algorithm to trust the odometry data more, leading to smaller corrections from the landmarks. However, if it were too small, the path will match very closely the odometry data, which is not the case.

It can be seen that on the leftmost part the uncertainties are the biggest, which may be caused by the increased velocity and the dependency of this choice of M only on velocity.

When we tried the same choice of M for the velocity model, the results were also good. They are shown on Fig. 4. It can be seen that the path depicted here goes more closely to the points on

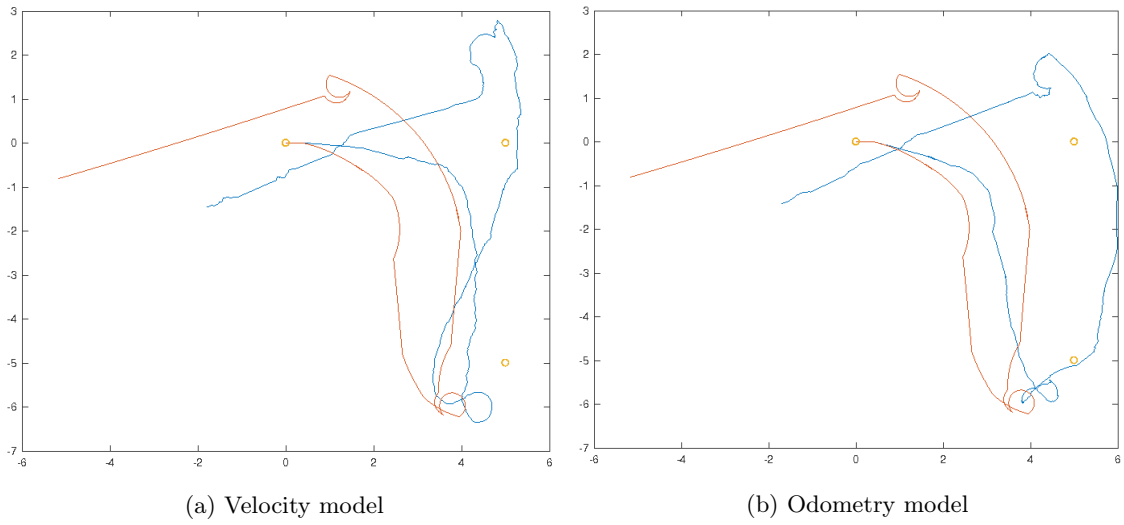

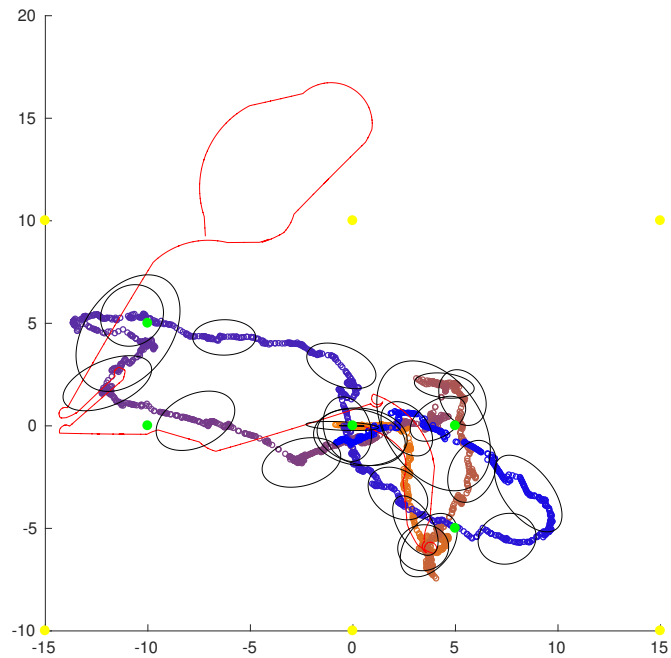

Figure 1: Comparison of a velocity and odometry model (in blue) for the first 3 marks. For both - M is the optimal found for the odometry model (reduced for velocity model). The red line represents the odometry measurements.

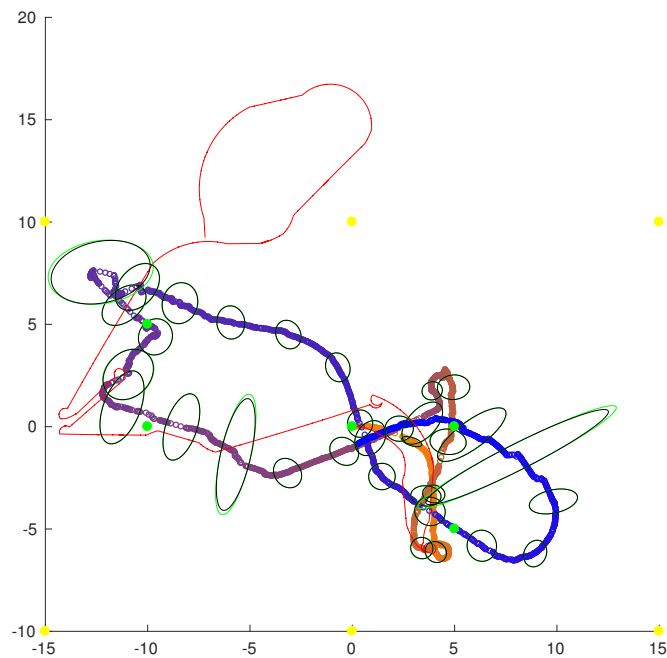

(a)

Figure 2: Trajectory(blue lines) and location uncertainties(black ellipses) on the estimated trajectory, using $M = 1.5I$. The trajectory from the odometry measurements is shown in red. Marks are shown in green, landmarks - in yellow.

(a)

Figure 3: Location uncertainties on the estimated trajectory, using the best found M . The trajectory from the odometry measurements is shown in red. Marks are shown in green, landmarks - in yellow.

(a)

Figure 4: Location uncertainties of the velocity model before (green ellipses) and after (black ellipses) correction on the estimated trajectory (orange-blue line), using best found M . The trajectory from the odometry measurements is shown in red. Marks are shown in green, landmarks - in yellow.

the left. However, the movement in the beginning is not modeled correctly, as it is seen that the first marked is missed by a lot. It can also be seen that this model's covariances can grow much bigger. This is to be expected, as the odometry model does not plan the position and can rely on the immediate odometry measurements.

The plotting of the uncertainties was done with two implementation separately - one is our own and one is the "error ellipse" function, taken from Matlab File Exchange. Both yielded the same result.

All the code is shown at the end of this document.

2 Task 2

Now the landmarks' positions are considered unknown, therefore changes have to be made to the algorithm in order to estimate their location. The implementation discussed next works with initially unknown number of landmarks. However, note that the assumption of known correspondences between a landmark and a measurement is still present. For the solution, we use the EKF SLAM algorithm, described in detail in Table 10.1

Extending the previous model, the estimated positions for the tracked landmarks so far will also be included in the state vector, besides the robot's pose:

$$\mu_t = \begin{bmatrix} x \\ y \\ \theta \\ m_{1,x} \\ m_{1,y} \\ \vdots \\ m_{L,x} \\ m_{L,y} \end{bmatrix}$$

Here $(m_{i,x}, m_{i,y})$ is the estimated position of the i -th landmark and L is the number of landmarks tracked so far. In this state vector we choose not to represent the landmark signatures, as they are unnecessary when there are known correspondences.

At this point it should be noted that we use exactly the same odometry model explained in Task 1. We need to take into account the fact that only the robot's pose (x, y, θ) must be updated at the prediction step, therefore we use the same matrix Fx as described in the book's algorithm for the calculations.

An important feature of our implementation is that the size of our state is not fixed from the start, but it is updated as new landmarks are seen by the robot. More specifically, when we have a measurement $z = (r, \phi)$ for a new landmark, the initial estimation of its location (l_x, l_y) is given by:

$$\begin{bmatrix} l_x \\ l_y \end{bmatrix} = \begin{bmatrix} m_{t,x} + r \cos(m_{t,\theta} + \phi) \\ m_{t,y} + r \sin(m_{t,\theta} + \phi) \end{bmatrix}$$

also known as the *inverse observation model*. This location is then appended to the end of the state vector m_t . But the covariance Σ of the state must also be extended by 2 rows/columns for uncertainty of the new landmark. Therefore, if M_{n+1} is a new landmark, then the new covariance is going to be

$$\Sigma = \begin{bmatrix} \Sigma_R & \Sigma_{R,M_1} & \cdots & \Sigma_{R,M_n} & \Sigma_{R,M_{n+1}} \\ \Sigma_{M_1,R} & \Sigma_{M_1} & \cdots & \Sigma_{M_1,M_n} & \Sigma_{M_1,M_{n+1}} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \Sigma_{M_n} & \Sigma_{M_n,M_1} & \cdots & \Sigma_{M_n} & \Sigma_{R,M_{n+1}} \\ \Sigma_{M_{n+1},R} & \Sigma_{M_{n+1},M_1} & \cdots & \Sigma_{M_{n+1},M_n} & \Sigma_{M_{n+1}} \end{bmatrix}, \quad \begin{aligned} \Sigma_{M_{n+1}} &= G_R \Sigma_R G_R^T + G_z Q G_z^T \\ \Sigma_{M_{n+1},M_i} &= G_R \Sigma_{R,M_i} \\ \Sigma_{M_{n+1},R} &= G_R \Sigma_R \end{aligned}$$

where G_R and G_z are the Jacobians of the *inverse observation model* with respect to the robot pose $(m_{t,x}, m_{t,y}, m_{t,\theta})$ and the measurement (r, ϕ) respectively:

$$G_R = \begin{bmatrix} 1 & 0 & -r \sin(m_{t,\theta} + \phi) \\ 0 & 1 & r \cos(m_{t,\theta} + \phi) \end{bmatrix}, \quad G_z = \begin{bmatrix} \cos(m_{t,\theta} + \phi) & -r \sin(m_{t,\theta} + \phi) \\ \sin(m_{t,\theta} + \phi) & r \cos(m_{t,\theta} + \phi) \end{bmatrix}$$

On Figure 5 two simulation of the algorithm are shown until the robot reaches the 8th landmark, hence it travels on at least one 8-like path. The first one has the default given noise for the motion, $M = 0.15 * I$ and the other one uses same optimal noise from task 1. As we can see the locations of the landmarks are correctly predicted and the trajectory is roughly correctly estimated. As expected when the motion noise is smaller, which is our case when we use the optimal M, then the uncertainty also decreases. For better visualization, the second trajectory with the before and after measurement uncertainties is plotted on Fig. 6. As before, the updates seem to be small, except for some cases on the first half of the eight, where the already seen landmarks with established

(a) $M = 0.15 * I$

(b) Optimal M

Figure 5: Estimated trajectories and position uncertainties for EKF SLAM. The six blue points are the true landmarks, with their estimated uncertainties. Orange trajectory represents the odometry metrics, the red-blue trajectory - the estimated one, together with its uncertainties after correction.

Figure 6: A close up of the trajectory (red-blue points, start is from red), estimated from EKF SLAM on the best found M , with uncertainties before (green ellipses) and after (black ellipses) correction. Red trajectory represents odometry measurements. The green points are the marks.

positions help reduce big uncertainties caused by higher velocity in one step. It can also be seen how on the second part of the eight shape the uncertainties are decreasing as a result of more certain positions of landmarks which are visible.

On Figure 7 a plot with the estimated landmark positions through time is shown. As we can see, the uncertainty of the landmarks is big when they are first seen, due to the uncertainty of the measurements, but by the end of the simulation it gets significantly smaller after multiple observations.

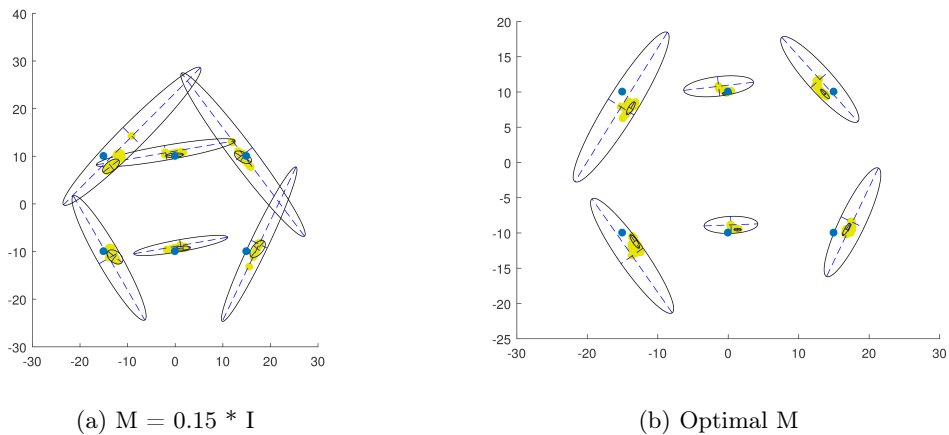

Figure 7: Landmark estimation through time. The uncertainties when a landmark is first seen (big ellipse) and at the end of the simulation (small ellipse) are displayed. The blue dots are the true positions

All the used Matlab code is shown at the end of this document.

2.1 Improvements

Many improvements can be applied to the default EKF SLAM algorithm in order to make it more efficient in more a practical setting.

One of those techniques is named the *provisional landmark list* and deals with *outliers* in the measurements. *Outliers* are essentially landmarks that are measured at unexpected locations. So instead of immediately adding them to the current state, they are added to a second list, the *provisional landmark list*. This list is like a parallel map to the original one, but its landmarks do not affect the robot pose. Once the uncertainty of a landmark in this list decreases enough, it is moved to the original map.

Another improvement to the algorithm is to keep *landmark existence probabilities*. When a landmark is seen, an internal value for that landmark is increased, signifying its existence. But if it is not seen in the position that it is expected to be, this value is decreased and if it goes beneath a threshold, then the landmark is removed.

Our implementation already contains one improvement over the default EKF SLAM algorithm. In the original EKF SLAM algorithm, when a new landmark is added its uncertainty is set to a very high value. What can be done instead, is to initialize it directly with the actual landmark uncertainty, as explained above. This reduces the numerical instabilities caused by the huge covariance.

The source code with the updated model and the plotting functions is shown below.

3 Code

3.1 Task 1

The modified function from Task 1, working with M , defined with alphas (as parameters) is given. The same function, but with modified definition of M and input parameters is used for using $M = u_{error}I$ for some given u_{error} .
