Preference Representation

Collective decision making is driven by the interests of individuals, who must be able to communicate preferences (directly through full revelation, or indirectly via “moves” in a game).

- So far, we have treated this topic only very abstractly, by saying that agents “have” a utility function or “report” a ranking.

- Preferences representation in combinatorial domains:
  - electing a committee of size $k$ from amongst $n$ candidates requires expressing preferences over $\binom{n}{k}$ possible committees;
  - negotiation over $n$ goods requires expressing preferences over $2^n$ alternative bundles.

- In this lecture, we are going to review and compare different preference representation languages.

Plan for Today

- General requirements on preference representation languages
- Distinguish cardinal and ordinal preference structures
- Different classes of utility functions (cardinal preferences): monotonic, dichotomous, modular, concave utilities...
- Review of languages for representing utility functions: explicit form, $k$-additive form, weighted goals, ...
- Discussion of properties of different representation languages: expressive power and comparative succinctness
- Review of languages for ordinal preference representation: prioritised goals and ceteris paribus preferences

Preference Representation Languages

The following questions should be addressed when you investigate a preference representation language:

- Cognitive relevance: How close is a given language to the way in which humans would express their preferences?
- Elicitation: How difficult is it to elicit the preferences of an agent so as to represent them in the chosen language?
- Expressive power: Can the chosen language encode all the preference structures we are interested in?
- Succinctness: Is the representation of (typical) structures succinct? Is one language more succinct than the other?
- Complexity: What is the computational complexity of related decision problems, such as comparing two alternatives?

We are going to concentrate on expressive power and succinctness.
Cardinal and Ordinal Preferences

A preference structure represents an agent’s preferences over a set of alternatives $X$. There are different types of preference structures:

- A **cardinal** preference structure is a (utility or valuation) function $u : X \rightarrow \text{Val}$, where Val is usually a set of numerical values such as $\mathbb{N}$ or $\mathbb{R}$.
- An **ordinal** preference structure is a binary relation $\preceq$ over the set of alternatives (reflexive, transitive and connected).

Note that we shall assume that $X$ is finite.

Preferences in Resource Allocation Scenarios

Let $\mathcal{R}$ be a finite set of indivisible resources (goods) with $|\mathcal{R}| = n$.

Assume there are no externalities: agent preferences only depend on their assigned bundle (not on, say, the allocation as a whole) $\sim$ need to model preference structures over $\mathcal{X} = 2^\mathcal{R}$.

Hence, the explicit representation has exponential space complexity.

Possible ways out:

- only consider restricted classes of preference structures, which may allow for a more concise representation; and/or
- consider (and compare) different representation languages.

We start with the case of utility functions . . .

Some Observations

- **Intrapersonal comparison**: ordinal and cardinal preferences allow for comparing the satisfaction of an agent for different alternatives
- **Interpersonal comparison**: ordinal preferences don’t allow for interpersonal comparison (“Ann likes $x$ more than Bob likes $y$”)
- **Preference intensity**: ordinal preferences cannot express preference intensity; cardinal preferences can (subject to Val being numerical)
- **Representability**: a connected ordinal preference relation $\preceq$ is representable by a utility function $u$: $x \preceq y$ iff $u(x) \leq u(y)$
- **Cognitive relevance**: hard to make general statements, but at least ordinal preferences don’t require reasoning with numerical utilities
- **Explicit representation**: the explicit representation of cardinal and ordinal preferences have space complexity $O(|\mathcal{X}|)$ resp. $O(|\mathcal{X}|^2)$

Classes of Utility Functions

Now a utility function is a mapping $u : 2^\mathcal{R} \rightarrow \mathbb{R}$.

- $u$ is **normalised** iff $u(\emptyset) = 0$
- $u$ is **non-negative** iff $u(X) \geq 0$
- $u$ is **monotonic** iff $u(X) \leq u(Y)$ whenever $X \subseteq Y$
- $u$ is **dichotomous** iff $u(X) = 0$ or $u(X) = 1$
- $u$ is **modular** iff $u(X \cup Y) = u(X) + u(Y) - u(X \cap Y)$
- $u$ is **additive** iff $u(X) = \sum_{x \in X} u(\{x\})$

Important: For the above definitions, the respective (in)equalities are understood to hold for all bundles $X, Y \subseteq \mathcal{R}$.

- What is the connection between modular and additive utilities?
Modular and Additive Utilities

Modularity and additivity are really just two different names for the same thing (well, almost):

**Proposition 1** A utility function is additive iff it is both modular and normalised.

**Proof:** “⇒”: obvious ✓

“⇐”: Let \( X \subseteq \mathcal{R} \), \( x \in X \).
From modularity, we get \( u(X) = u(X \setminus \{x\}) + u(\{x\}) \). As \( u \) is normalised, we obtain \( u(X) = u(X \setminus \{x\}) + u(\{x\}) \).
If we iterate this step \(|X|\) times, we get \( u(X) = \sum_{x \in X} u(\{x\}) \). ✓

More Classes of Utility Functions

A few more commonly used classes of utility functions:

- \( u \) is **submodular** iff \( u(X \cup Y) \leq u(X) + u(Y) - u(X \cap Y) \)
- \( u \) is **supermodular** iff \( u(X \cup Y) \geq u(X) + u(Y) - u(X \cap Y) \)
- \( u \) is **concave** iff \( u(X \cup Y) - u(Y) \leq u(X \cup Z) - u(Z) \) for \( Y \supseteq Z \)
  - Intuition: marginal utility (of obtaining \( X \)) decreases as we move to a better starting position (namely from \( Z \) to \( Y \))
- \( u \) is **convex** iff \( u(X \cup Y) - u(Y) \geq u(X \cup Z) - u(Z) \) for \( Y \supseteq Z \)

Observations

The following relationships amongst some of these classes of utility functions are easily checked:

- submodular \( \cap \) supermodular = modular
- \( u \) submodular iff \( -u \) supermodular
- \( u \) concave iff \( -u \) convex
- concave \( \subseteq \) submodular (Proof: set \( Z = X \cap Y \))
- convex \( \subseteq \) supermodular

Explicit Representation

The **explicit form** of representing a utility function \( u \) consists of a table listing for every bundle \( X \subseteq \mathcal{R} \) the utility \( u(X) \).
By convention, table entries with \( u(X) = 0 \) may be omitted.

- the explicit form is **fully expressive**:
  - any utility function \( u : 2^\mathcal{R} \rightarrow \mathbb{R} \) may be so described
- the explicit form is **not concise**:
  - it may require up to \( 2^n \) entries

Even very simple utility functions may require exponential space: e.g., the additive function mapping bundles to their cardinality.

**Remark:** Of course, any additive utility function could be encoded very concisely: just store the utilities for individual goods + the information that this is an additive function \( \sim \) linear space
But this is **not a general method** (not fully expressive).
The \(k\)-additive Form

- A utility function is \(k\)-additive iff the utility assigned to a bundle \(X\) can be represented as the sum of marginal utilities for subsets of \(X\) with cardinality \(\leq k\) (limited synergies).
- The \(k\)-additive form of representing utility functions:
  \[ u(X) = \sum_{T \subseteq X} \alpha^T \text{ with } \alpha^T = 0 \text{ whenever } |T| > k \]

Example: \(u = 3x_1 + 7x_2 - 2x_2x_3\) is a 2-additive function

That is, specifying a utility function in this language means specifying the coefficients \(\alpha^T\) for bundles \(T \subseteq \mathcal{R}\).

In the context of resource allocation, the value \(\alpha^T\) can be seen as the additional benefit incurred from owning the items in \(T\) together, i.e. beyond the benefit of owning all proper subsets.

Comparative Succinctness

If two languages can express the same class of utility functions, which should we use? An important criterion is succinctness.

Let \(L\) and \(L'\) be two languages for defining utilities. We say that \(L'\) is at least as succinct as \(L\), denoted by \(L \preceq L'\), iff there exist a mapping \(f : L \rightarrow L'\) and a polynomial function \(p\) such that:
- \(u \equiv f(u)\) for all \(u \in L\) (they represent the same functions); and
- \(\text{size}(f(u)) \leq p(\text{size}(u))\) for all \(u \in L\) (polysize reduction).

Write \(L < L'\) (strictly less succinct) iff \(L \preceq L'\) but not \(L' \preceq L\).

Two languages can also be incomparable in view of succinctness.

Expressive Power

The \(k\)-additive form is fully expressive, if we choose \(k\) large enough:

**Proposition 2** Any utility function is representable in \(k\)-additive form for some \(k \leq |\mathcal{R}|\).

**Proof:** For any utility function \(u\), we can define coefficients \(\alpha^X:\)
- \(\alpha^{\{\}} = u(\{\})\)
- \(\alpha^X = u(X) - \sum_{T \subseteq X} \alpha^T\) for all \(X \subseteq \mathcal{R}\) with \(X \neq \{\}\)

Hence, \(u(X) = \sum_{T \subseteq X} \alpha^T\), which is \(k\)-additive for \(k = |\mathcal{R}|\).

The \(k\)-additive form allows for a parametrisation of synergies:
- \(1\)-additive = modular (no synergies)
- \(|\mathcal{R}|\)-additive = general (any kind of synergies)
- ... and everything in between

Explicit vs. \(k\)-additive Form

**Proposition 3** The explicit and the \(k\)-additive form are incomparable in view of succinctness.

**Proof sketch:** The following two functions can be used to prove the mutual lack of a polysize reduction:
- \(u_1(X) = |X|\): representing \(u_1\) requires \(|\mathcal{R}|\) non-zero coefficients in the \(k\)-additive form (linear); but \(2^{|\mathcal{R}|} - 1\) non-zero values in the explicit form (exponential).
- \(u_2(X) = 1\) for \(|X| = 1\) and \(u_2(X) = 0\) otherwise: requires \(|\mathcal{R}|\) non-zero values in the explicit form (linear); but \(2^{|\mathcal{R}|} - 1\) non-zero coefficients in the \(k\)-additive form (exponential):
  \[ \alpha^T = 1 \text{ for } |T| = 1, \alpha^T = -2 \text{ for } |T| = 2, \alpha^T = 3 \text{ for } |T| = 3, \ldots \]

**Weighted Propositional Formulas**

An alternative approach to preference representation is based on weighted propositional formulas...

**Notation:** finite set of propositional letters $PS$ (representing goods); propositional language $L_{PS}$ over $PS$ can describe requirements.

A **goal base** is a set $G = \{(\varphi_i, \alpha_i)\}$ of pairs, each consisting of a consistent propositional formula $\varphi_i \in L_{PS}$ and a real number $\alpha_i$.

The utility function $u_G$ generated by $G$ is defined by

$$u_G(M) = \sum \{ \alpha_i \mid (\varphi_i, \alpha_i) \in G \text{ and } M \models \varphi_i \}$$

for all models $M \in 2^{PS}$. $G$ is called the **generator** of $u_G$.

- If we restrict goals to **conjunctions of atoms** (of length $\leq k$), then this corresponds directly to the $k$-additive form.

---

**Ordinal Preferences**

Next we are going to look into different languages for representing **ordinal** preference structures.

Recall that an *explicit representation* of an ordinal preference relation $\preceq$ over $2^n$ alternatives requires space up to $O(2^n \cdot 2^n)$: for each pair of bundles, say which one is preferred.

---

**Program-based Representations**

Yet another approach to representing preferences would be to define utilities in terms of a **program**: input bundle, output utility value.

But not just any program will do. Requirements:

- it must be possible to efficiently validate that a given string constitutes a **syntactically correct program**; and
- we have to have an effective method of **computing the output** of the program for any given input.

Dunne *et al*. (2005) propose such a program-based approach based on so-called **straight-line programs** (warning: rather technical).

One result says that any function computable by a deterministic TM in time $T$ is representable by an SLP with $O(T \log T)$ lines.

---

**Prioritised Goals**

Again, associate goods with propositional letters in $PS$ and bundles with models $M \in 2^{PS}$. Goals can be expressed as formulas in the propositional language $L_{PS}$.

Instead of weights, we now have a **priority relation** over goals. Assuming this priority relation is a total order, it can be represented by a function $\text{rank} : \mathbb{N} \rightarrow \mathbb{N}$ mapping each (index of a) goal to its rank. By convention, a **lower rank** means **higher priority**.

A **goal base** is now a finite set of goals with an associated rank function: $G = (\{\varphi_1, \ldots, \varphi_m\}, \text{rank})$.

- Ideally, all goals will get satisfied. But if not, how can we extend a priority relation over goals to a preference relation over models?
Combining Priorities

There are several options (convention: $\min(\{\}) = +\infty$):

- **Best-out ordering:**
  
  $M \preceq M'$ iff $\min\{\text{rank}(i) \mid M \not\models \varphi_i\} \leq \min\{\text{rank}(i) \mid M' \not\models \varphi_i\}$

  That is, preference depends (only) on the rank of the most important goal that is being violated.

- **Discrimin ordering:**

  Let $d(M, M') = \min\{\text{rank}(i) \mid M \not\models \varphi_i \text{ and } M' \models \varphi_i\}$ be the rank of the most important “discriminating” goal.

  $M \preceq M'$ iff $d(M, M') \leq d(M', M)$ or

  \[
  \{\varphi_i \mid M \models \varphi_i\} = \{\varphi_i \mid M' \models \varphi_i\}
  \]

Combining Priorities (cont.)

- **Leximin ordering:**

  Let $d_k(M) = |\{\varphi_i \mid M \models \varphi_i \text{ and } \text{rank}(\varphi_i) = k\}|$ be the number of goals of rank $k$ that are satisfied by alternative $M$.

  $M \preceq M'$ iff

  1. for all $k$: $d_k(M) = d_k(M')$ or
  2. there exists a $k$ such that $d_k(M) < d_k(M')$ and for all $j < k$: $d_j(M) = d_j(M')$

Properties

- None of the three variants of combining prioritised goals leads to a fully expressive preference representation language.

- The best-out ordering and the leximin ordering result in connected preference relations, but the discrimin ordering typically does not.

- For the strict preference relations we have:
  1. best-out preference entails discrimin preference; and
  2. discrimin preference entails leximin preference

Ceteris Paribus Preferences

In the language of ceteris paribus preferences, preferences are expressed as statements of the form $C : \varphi > \varphi'$, meaning:

“If $C$ is true, all other things being equal, I prefer alternatives satisfying $\varphi \land \neg \varphi'$ over those satisf. $\neg \varphi \land \varphi'$.”

The “other things” are the truth values of the propositional variables not occurring in $\varphi$ and $\varphi'$. A preference relation can be constructed as the transitive closure of the union of individual preference statements.

Discussion: interesting from a cognitive point of view (close to human intuition), but of rather high complexity.

An important sublanguage of ceteris paribus preferences, imposing various restrictions on goals, are CP-nets.

Summary

We have reviewed several preference representation languages for both cardinal and ordinal preference structures.

- The computational aspects of preference representation are crucial in **combinatorial domains** (such as resource allocation).
- We have emphasised **expressive power** and **succinctness**.
- Languages considered (there are many more):
  - **cardinal**: explicit form, $k$-additive form, weighted goals, and program-based representations of utility functions
  - **ordinal**: prioritised goals and ceteris paribus statements
