# Lectures on the modal $\mu\text{-calculus}$

Yde Venema<sup>\*</sup>

©YV 2024

## Abstract

These notes give an introduction to the theory of the modal  $\mu$ -calculus.

## 1 Basic Modal Logic

As mentioned in the preface, we assume familiarity with the basic definitions concerning the syntax and semantics of modal logic. The purpose of this first chapter is to briefly recall notation and terminology. We focus on some aspects of modal logic that feature prominently in its extensions with fixpoint operators.

**Convention 1.1** Throughout this text we let Prop be a countably infinite set of *propositional* variables, whose elements are usually denoted as p, q, r, x, y, z, ..., and we let D be a finite set of (atomic) actions, whose elements are usually denoted as d, e, c, ... We will usually focus on a finite subset P of Prop, consisting of those propositional variables that occur freely in a particular formula. In practice we will often suppress explicit reference to Prop, P and D.

### 1.1 Basics

#### Structures

▶ Introduce LTSs as process graphs

**Definition 1.2** A (labelled) transition system, LTS, or (Kripke) model of type (P, D) is a triple  $\mathbb{S} = \langle S, V, R \rangle$  such that S is a set of objects called states or points,  $V : \mathbb{P} \to \wp(S)$  is a valuation, and  $R = \{R_d \subseteq S \times S \mid d \in \mathbb{D}\}$  is a family of binary accessibility relations. In case D is a singleton, we will simply write R for the unique accessibility relation in a model.

Elements of the set  $R_d[s] := \{t \in S \mid (s,t) \in R_d\}$  are called *d*-successors of *s*. A transition system is called *image-finite* or *finitely branching* if  $R_d[s]$  is finite, for every  $d \in \mathsf{D}$  and  $s \in S$ .

A *pointed* transition system or Kripke model is a pair  $(\mathbb{S}, s)$  consisting of a transition system  $\mathbb{S}$  and a designated state s in  $\mathbb{S}$ .

**Remark 1.3** It will occasionally be convenient to work with an alternative, *coalgebraic* presentation of transition systems. Intuitively, it should be clear that instead of having a valuation  $V : \mathsf{P} \to \wp(S)$ , telling us at which states each proposition letter is true, we could just as well have a *marking*  $\sigma_V : S \to \wp(\mathsf{P})$  informing us which proposition letters are true at each state. Also, a binary relation R on a set S can be represented as a map  $R[\cdot] : S \to \wp(S)$  mapping a state s to the collection R[s] of its successors. In this line, a family  $R = \{R_d \subseteq S \times S \mid d \in \mathsf{D}\}$  of accessibility relations can be seen as a map  $\sigma_R : S \to \wp(S)^{\mathsf{D}}$ , where  $\wp(S)^{\mathsf{D}}$  denotes the set of maps from  $\mathsf{D}$  to  $\wp(S)$ .

Combining these two maps into one single function, we see that a transition system  $\mathbb{S} = \langle S, V, R \rangle$  of type (P, D) can be seen as a pair  $\langle S, \sigma \rangle$ , where  $\sigma : S \to \wp(\mathsf{P}) \times \wp(S)^{\mathsf{D}}$  is the map given by  $\sigma(s) := (\sigma_V(s), \sigma_R(s)).$ 

For future reference we define the notion of a Kripke functor.

**Definition 1.4** Fix a set P of proposition letters and a set D of atomic actions. Given a set S, let  $K_{D,P}S$  denote the set

$$\mathsf{K}_{\mathsf{D},\mathsf{P}}S := \wp(\mathsf{P}) \times \wp(S)^{\mathsf{D}}.$$

This operation will be called the *Kripke functor* associated with D and P.

A typical element of  $\mathsf{K}_{\mathsf{D},\mathsf{P}}S$  will be denoted as  $(\pi, X)$ , with  $\pi \subseteq \mathsf{P}$  and  $X = \{X_d \mid d \in \mathsf{D}\}$ with  $X_d \subseteq S$  for each  $d \in \mathsf{D}$ .

When we take this perspective we will sometimes refer to Kripke models as  $K_{D,P}S$ coalgebras or Kripke coalgebras.

Given this definition we may summarize Remark 1.3 by saying that any transition system can be presented as a pair  $\mathbb{S} = \langle S, \sigma : S \to \mathsf{K}S \rangle$  where  $\mathsf{K}$  is the Kripke functor associated with  $\mathbb{S}$ . In practice, we will usually write  $\mathsf{K}$  rather than  $\mathsf{K}_{\mathsf{D},\mathsf{P}}$ .

#### Syntax

Working with fixpoint operators, we may benefit from a set-up in which the use of the negation symbol may only be applied to atomic formulas. The price that one has to pay for this is an enlarged arsenal of primitive symbols. In the context of modal logic we then arrive at the following definition.

**Definition 1.5** The language ML<sub>D</sub> of *polymodal logic* in D is defined as follows:

 $\varphi \, ::= \, p \, \mid \, \overline{p} \, \mid \, \bot \, \mid \, \top \, \mid \, \varphi \lor \varphi \, \mid \, \varphi \land \varphi \, \mid \, \diamondsuit_d \varphi \, \mid \, \Box_d \varphi$ 

where  $p \in \mathsf{Prop}$ , and  $d \in \mathsf{D}$ . Elements of  $\mathsf{ML}_{\mathsf{D}}$  are called *(poly-)modal formulas*, or briefly, *formulas*. In case the set  $\mathsf{D}$  is a singleton, we speak of the language  $\mathsf{ML}$  of *basic modal logic* or *monomodal* logic; in this case we will denote the modal operators by  $\diamond$  and  $\Box$ , respectively.

Given a finite set P of propositional variables, we let  $\texttt{ML}_D(P)$  denote the set of formulas in which only variables from P occur.  $\lhd$ 

Often the sets P and D are implicitly understood, and suppressed in the notation. Generally it will suffice to treat examples, proofs, etc., from monomodal logic.

We will need some definitions and notations concerning atomic formulas.

**Definition 1.6** Let P be a set of propositional variables. We define the sets Lit(P) and At(P) of, respectively, *literals* and *atomic formulas over* P as follows:

We will generally use the symbol  $\ell$  to denote an arbitrary literal.

**Remark 1.7** The *negation*  $\sim \varphi$  of a formula  $\varphi$  can inductively be defined as follows:

On the basis of this, we can also define the other standard abbreviated connectives, such as  $\rightarrow$  and  $\leftrightarrow$ .

We assume that the reader is familiar with standard syntactic notions such as those of a *subformula* or the *construction tree* of a formula, and with standard syntactic operations such as *substitution*. Concerning the latter, we let  $\varphi[\psi/p]$  denote the formula that we obtain by substituting all occurrences of p in  $\varphi$  by  $\psi$ .

**Definition 1.8** We define the collection  $Sf(\xi)$  of subformulas of a modal formula  $\xi$  by the following induction on the complexity of  $\xi$ :

We write  $\varphi \leq \psi$  to denote that  $\varphi$  is a subformula of  $\psi$ . The *size* of a formula  $\xi$  is defined as the number of its subformulas,  $|\xi| := |Sf(\xi)|$ .

#### Semantics

The *relational* semantics of modal logic is well known. The basic idea is that the modal operators  $\diamond_d$  and  $\Box_d$  are both interpreted using the *accessibility* relation  $R_d$ .

The notion of truth (or satisfaction) is defined as follows.

**Definition 1.9** Let  $\mathbb{S} = \langle S, \sigma \rangle$  be a transition system of type (P, D). Then the *satisfaction* relation  $\Vdash$  between states of  $\mathbb{S}$  and formulas of  $ML_D(P)$  is defined by the following formula induction.

We say that  $\varphi$  is true or holds at s if  $\mathbb{S}, s \Vdash \varphi$ , and we let the set

$$\llbracket \varphi \rrbracket^{\mathbb{S}} := \{ s \in S \mid \mathbb{S}, s \Vdash \varphi \}.$$

denote the meaning or extension of  $\varphi$  in S.

Alternatively (but equivalently), one may define the semantics of modal formulas directly in terms of this meaning function  $\llbracket \varphi \rrbracket^{\mathbb{S}}$ . This approach has some advantages in the context of fixpoint operators, since it brings out the role of the powerset algebra  $\wp(S)$  more clearly.

 $\triangleleft$ 

**Remark 1.10** Fix an LTS S, then define  $\llbracket \varphi \rrbracket^{\mathbb{S}}$  by induction on the complexity of  $\varphi$ :

$$\begin{split} \llbracket p \rrbracket^{\mathbb{S}} &= V(p) & \llbracket \overline{p} \rrbracket^{\mathbb{S}} &= S \setminus V(p) \\ \llbracket \bot \rrbracket^{\mathbb{S}} &= \varnothing & \llbracket \varphi \rrbracket^{\mathbb{S}} \cup \llbracket \psi \rrbracket^{\mathbb{S}} & \llbracket \nabla \psi \rrbracket^{\mathbb{S}} &= S \\ \llbracket \varphi \vee \psi \rrbracket^{\mathbb{S}} &= \llbracket \varphi \rrbracket^{\mathbb{S}} \cup \llbracket \psi \rrbracket^{\mathbb{S}} & \llbracket \varphi \wedge \psi \rrbracket^{\mathbb{S}} &= \llbracket \varphi \rrbracket^{\mathbb{S}} \cap \llbracket \psi \rrbracket^{\mathbb{S}} \\ \llbracket \diamond_{d} \varphi \rrbracket^{\mathbb{S}} &= \langle R_{d} \rangle \llbracket \varphi \rrbracket^{\mathbb{S}} & \llbracket \Box_{d} \varphi \rrbracket^{\mathbb{S}} &= [R_{d}] \llbracket \varphi \rrbracket^{\mathbb{S}} \end{split}$$

Here the operations  $\langle R_d \rangle$  and  $[R_d]$  on  $\wp(S)$  are defined by putting

The satisfaction relation  $\Vdash$  may be recovered from this by putting  $\mathbb{S}, s \Vdash \varphi$  iff  $s \in \llbracket \varphi \rrbracket^{\mathbb{S}}$ .

**Definition 1.11** Let *s* and *s'* be two states in the transition systems S and S' of type (P, D), respectively. Then we say that *s* and *s'* are *modally equivalent*, notation:  $S, s \equiv_{(P,D)} S', s'$ , if *s* and *s'* satisfy the same modal formulas, that is,  $S, s \Vdash \varphi$  iff  $S', s' \Vdash \varphi$ , for all modal formulas  $\varphi \in ML_D(P)$ .

#### Flows, trees and streams

In some parts of these notes *deterministic* transition systems feature prominently.

**Definition 1.12** A transition system  $\mathbb{S} = \langle S, V, R \rangle$  is called *deterministic* if each  $R_d[s]$  is a singleton.

Note that our definition of determinism does not allow  $R_d = \emptyset$  for any point s. We first consider the monomodal case.

**Definition 1.13** Let P be a set of proposition letters. A deterministic monomodal Kripke model for this language is called a *flow model for* P, or a  $\wp(\mathsf{P})$ -*flow*. In case such a structure is of the form  $\langle \omega, V, Succ \rangle$ , where *Succ* is the standard successor relation on the set  $\omega$  of natural numbers, we call the structure a *stream model for* P, or a  $\wp(\mathsf{P})$ -*stream*.

In case the set D of actions is finite, we may just as well identify it with the set  $k = \{0, \ldots, k-1\}$ , where k is the size of D. We usually restrict to the binary case, that is, k = 2. Our main interest will be in Kripke models that are based on the *binary tree*, i.e., a tree in which every node has exactly two successors, a left and a right one.

**Definition 1.14** With  $2 = \{0, 1\}$ , we let  $2^*$  denote the set of finite strings of 0s and 1s. We let  $\varepsilon$  denote the empty string, while the left- and right successor of a node s are denoted by  $s \cdot 0$  and  $s \cdot 1$ , respectively. Written as a relation, we put

$$Succ_i = \{(s, s \cdot i) \mid s \in 2^*\}.$$

A binary tree over  $\mathsf{P}$ , or a binary  $\wp(\mathsf{P})$ -tree is a Kripke model of the form  $\langle 2^*, V, Succ_0, Succ_1 \rangle$ .

**Remark 1.15** In the general case, the *k*-ary tree is the structure  $(k^*, Succ_0, \ldots, Succ_{k-1})$ , where  $k^*$  is the set of finite sequences of natural numbers smaller than k, and  $Succ_i$  is the *i*-th successor relation given by

$$Succ_i = \{(s, s \cdot i) \mid s \in k^*\}.$$

A k-flow model is a Kripke model  $\mathbb{S} = \langle S, V, R \rangle$  with k many deterministic accessibility relations, and a k-ary tree model is a k-flow model which is based on the k-ary tree.

In deterministic transition systems, the distinction between boxes and diamonds evaporates. It is then convenient to use a single symbol  $\bigcirc_i$  to denote either the box or the diamond.

**Definition 1.16** The set  $MFL_k(P)$  of formulas of *k*-ary Modal Flow Logic in P is given as follows:

$$\varphi \, ::= \, p \, \mid \, \overline{p} \, \mid \, \bot \, \mid \, \top \, \mid \, \varphi \lor \varphi \, \mid \, \varphi \land \varphi \, \mid \, \bigcirc_i \varphi$$

where  $p \in \mathsf{P}$ , and i < k. In case k = 1 we will also speak of *modal stream logic*, notation: MSL( $\mathsf{P}$ ).

#### **1.2** Game semantics

We will now describe the semantics defined above in game-theoretic terms. That is, we will define the *evaluation game*  $\mathcal{E}(\xi, \mathbb{S})$  associated with a (fixed) formula  $\xi$  and a (fixed) LTS  $\mathbb{S}$ . This game is an example of a *board game*. In a nutshell, board games are games in which the players move a token along the edge relation of some graph, so that a *match* of *play* of the game corresponds to a (finite or infinite) path through the graph. Furthermore, the winning conditions of a match are determined by the nature of this path. We will meet many examples of board games in these notes, and in Chapter 5 we will study them in more detail.

The evaluation game  $\mathcal{E}(\xi, \mathbb{S})$  is played by two *players*: Éloise ( $\exists$  or 0) and Abélard ( $\forall$  or 1). Given a player  $\sigma$ , we always denote the *opponent* of  $\sigma$  by  $\overline{\sigma}$ . As mentioned, a *match* of the game consists of the two players moving a *token* from one position to another. *Positions* are of the form ( $\varphi, s$ ), with  $\varphi$  a *subformula* of  $\xi$ , and s a state of  $\mathbb{S}$ .

It is useful to assign *goals* to both players: in an arbitrary position  $(\varphi, s)$ , think of  $\exists$  trying to show that  $\varphi$  is *true* at s in S, and of  $\forall$  of trying to convince her that  $\varphi$  is *false* at s.

Depending on the type of the position (more precisely, on the formula part of the position), one of the two players may move the token to a next position. For instance, in a position of the form ( $\diamond_d \varphi, s$ ), it is  $\exists$ 's turn to move, and she must choose an arbitrary *d*-successor *t* of *s*, thus making ( $\varphi, t$ ) the next position. Intuitively, the idea is that in order to show that  $\diamond \varphi$  is true at *s*,  $\exists$  has to come up with a successor of *s* where  $\varphi$  holds. Formally, we say that the set of (*admissible*) next positions that  $\exists$  may choose from is given as the set  $\{(\varphi, t) \mid t \in R_d[s]\}$ . In the case there is no successor of *s* to choose, she immediately loses the game. This is a convenient way to formulate the rules for winning and losing this game: if a position ( $\varphi, s$ ) has no admissible next positions, the player whose turn it is to play at ( $\varphi, s$ ) gets stuck and immediately loses the game.

This convention gives us a nice handle on positions of the form (p, s) where p is a proposition letter: we always assign to such a position an *empty* set of admissible moves, but we

Position	Player	Admissible moves
$(\varphi_1 \lor \varphi_2, s)$		$\{(\varphi_1, s), (\varphi_2, s)\}$
$(\varphi_1 \land \varphi_2, s)$	$\forall$	$\{(\varphi_1,s),(\varphi_2,s)\}$
$(\diamondsuit_d \varphi, s)$	Ξ	$\left  \{ (\varphi, t) \mid t \in R_d[s] \} \right $
$(\Box_d \varphi, s)$	$\forall$	$\{(\varphi,t) \mid t \in R_d[s]\}$
$(\perp, s)$	Ξ	Ø
( op, s)	$\forall$	Ø
$(p,s), s \in V(p)$	$\forall$	Ø
$(p,s), s \not \in V(p)$	Ξ	Ø
$(\overline{p},s),s\not\in V(p)$	$\forall$	Ø
$(\overline{p},s),s\in V(p)$	Ξ	Ø

Table 1	:	Evaluation	game	for	modal	logic
TODIO T	•	<b>L</b> falaation	Samo	TOT	modul	 CBIC.

make  $\exists$  responsible for (p, s) in case p is *false* at s, and  $\forall$  in case p is *true* at s. In this way,  $\exists$  immediately wins if p is true at s, and  $\forall$  if it is otherwise. The rules for the negative literals  $(\overline{p})$  and the constants,  $\bot$  and  $\top$ , follow a similar pattern.

The full set of rules of the game is given in Table 1. Observe that all matches of this game are finite, since at each move of the game the active formula is reduced in size. (From the general perspective of board games, this means that we need not worry about winning conditions for matches of infinite length.) We may now summarize the game as follows.

**Definition 1.17** Given a modal formula  $\xi$  and a transition system  $\mathbb{S}$ , the evaluation game  $\mathcal{E}(\xi, \mathbb{S})$  is defined as the board game given by Table 1, with the set  $Sf(\xi) \times S$  providing the positions of the game; that is, a position is a pair consisting of a subformula of  $\xi$  and a point in  $\mathbb{S}$ . The instantiation of this game with starting point  $(\xi, s)$  is denoted as  $\mathcal{E}(\xi, \mathbb{S})@(\xi, s)$ .

An *instance* of an evaluation game is a pair consisting of an evaluation game and a *starting position* of the game. Such an instance will also be called an *initialized game*, or sometimes, if no confusion is likely, simply a game.

A strategy for a player  $\sigma$  in an initialized game is a method that  $\sigma$  uses to select his moves during the play. Such a strategy is winning for  $\sigma$  if every match of the game (starting at the given position) is won by  $\sigma$ , provided  $\sigma$  plays according to this strategy. A position ( $\varphi$ , s) is winning for  $\sigma$  if  $\sigma$  has a winning strategy for the game initialized in that position. (Note that this definition applies to *all* positions, not only to the ones owned by  $\sigma$ .) The set of winning positions in  $\mathcal{E}(\xi, \mathbb{S})$  for  $\sigma$  is denoted as Win $_{\sigma}(\mathcal{E}(\xi, \mathbb{S}))$ .

The main result concerning these games is that they provide an alternative, but equivalent, semantics for modal logic.

▶ Example to be added

**Theorem 1.18 (Adequacy)** Let  $\xi$  be a modal formula, and let S be an LTS. Then for any state s in S it holds that

$$(\xi, s) \in \operatorname{Win}_{\exists}(\mathcal{E}(\xi, \mathbb{S})) \iff \mathbb{S}, s \Vdash \xi.$$

The proof of this Theorem is left to the reader.

#### **1.3** Bisimulations and bisimilarity

One of the most fundamental notions in the model theory of modal logic is that of a bisimulation between two transition systems.

▶ discuss bisimilarity as a notion of behavioral equivalence

**Definition 1.19** Let S and S' be two transition systems of the same type (P, D). Then a relation  $Z \subseteq S \times S'$  is a *bisimulation* of type (P, D) if the following hold, for every pair  $(s, s') \in Z$ .

(prop)  $s \in V(p)$  iff  $s' \in V'(p)$ , for all  $p \in \mathsf{P}$ ;

(forth) for all actions d, and for all  $t \in R_d[s]$  there is a  $t' \in R'_d[s']$  with  $(t, t') \in Z$ ;

(back) for all actions d, and for all  $t' \in R'_d[s']$  there is a  $t \in R_d[s]$  with  $(t, t') \in Z$ .

Two states s and s' are called *bisimilar*, notation:  $\mathbb{S}, s \bigoplus_{\mathsf{P},\mathsf{D}} \mathbb{S}', s'$  if there is some bisimulation Z of type  $(\mathsf{P},\mathsf{D})$  with  $(s,s') \in Z$ . If no confusion is likely to arise, we generally drop the subscripts, writing ' $\overleftrightarrow$ ' rather than ' $\overleftrightarrow_{\mathsf{P},\mathsf{D}}$ '.

#### Bisimilarity and modal equivalence

In order to understand the importance of this notion for modal logic, the starting point should be the observation that the truth of modal formulas is *invariant* under bisimilarity. Recall that  $\equiv$  denotes the relation of modal equivalence.

**Theorem 1.20 (Bisimulation Invariance)** Let S and S' be two transition systems of the same type. Then

$$\mathbb{S}, s \leftrightarrow \mathbb{S}', s' \Rightarrow \mathbb{S}, s \equiv \mathbb{S}', s'$$

for every pair of states s in  $\mathbb{S}$  and s' in  $\mathbb{S}'$ .

**Proof.** By a straightforward induction on the complexity of modal formulas one proves that bisimilar states satisfy the same formulas. QED

But there is much more to say about the relation between modal logic and bisimilarity than Theorem 1.20. In particular, for some classes of models, one may prove a converse statement, which amounts to saying that the notions of bisimilarity and modal equivalence coincide. Such classes are said to have the *Hennessy-Milner* property. As an example we mention the class of finitely branching transition systems.

**Theorem 1.21 (Hennessy-Milner Property)** Let S and S' be two finitely branching transition systems of the same type. Then

$$\mathbb{S}, s \leftrightarrow \mathbb{S}', s' \iff \mathbb{S}, s \equiv \mathbb{S}', s'$$

for every pair of states s in  $\mathbb{S}$  and s' in  $\mathbb{S}'$ .

**Proof.** The direction from left to right follows from Theorem 1.20. In order to prove the opposite direction, one may show that the relation  $\equiv$  of modal equivalence itself is a bisimulation. Details are left to the reader. QED

This theorem can be read as indication of the expressiveness of modal logic: any difference in behaviour between two states in finitely branching transition systems can in fact be witnessed by a concrete modal formula. As another witness to this expressivity, in section 1.5 we will see that modal logic is sufficiently rich to express all bisimulation-invariant first-order properties. Obviously, this result also adds considerable strength to the link between modal logic and bisimilarity.

As a corollary of the bisimulation invariance theorem, modal logic has the *tree model property*, that is, every satisfiable modal formula is satisfiable on a structure that has the shape of a tree.

**Definition 1.22** A transition system S of type (P, D) is called *tree-like* if the structure  $\langle S, \bigcup_{d \in D} R_d \rangle$  is a tree.

The key step in the proof of the tree model property of modal logic is the observation that every transition system can be 'unravelled' into a bisimilar tree-like model. The basic idea of such an unravelling is the new states encode (part of) the *history* of the old states. Technically, the new states are the *paths* through the old system.

**Definition 1.23** Let  $\mathbb{S} = \langle S, V, R \rangle$  be a transition system of type (P, D). A *(finite) path* through  $\mathbb{S}$  is a nonempty sequence of the form  $(s_0, d_1, s_1, d_2, \ldots, s_n)$  such that  $R_{d_i}s_{i-1}s_i$  for all i with  $0 < i \leq n$ . The set of paths through  $\mathbb{S}$  is denoted as  $Paths(\mathbb{S})$ ; we use the notation  $Paths_s(\mathbb{S})$  for the set of paths starting at s.

The unravelling of  $\mathbb{S}$  around a state s is the transition system  $\vec{\mathbb{S}}_s$  which is coalgebraically defined as the structure  $\langle Paths_s(\mathbb{S}), \vec{\sigma} \rangle$ , where the coalgebra map  $\vec{\sigma} = (\vec{\sigma}_V, (\vec{\sigma}_d \mid d \in \mathsf{D}))$  is given by putting

$$\vec{\sigma}_V(s_0, d_1, s_1, d_2, \dots, s_n) := \sigma_V(s_n), \vec{\sigma}_d(s_0, d_1, s_1, d_2, \dots, s_n) := \{(s_0, d_1, s_1, \dots, s_n, d, t) \in Paths_s(\mathbb{S}) \mid R_d s_n t\}$$

Finally, the unravelling of a pointed transition system  $(\mathbb{S}, s)$  is the pointed structure  $(\vec{\mathbb{S}}_s, s)$ , where (with some abuse of notation) we let s denote the path of length zero that starts and finishes at s.

Clearly, unravellings are tree-like structures, and any pointed transition system is bisimilar to its unravelling. But then the following theorem is immediate by Theorem 1.20.

**Theorem 1.24 (Tree Model Property)** Let  $\varphi$  be a satisfiable modal formula. Then  $\varphi$  is satisfiable at the root of a tree-like model.

#### **Bisimilarity** game

We may also give a game-theoretic characterization of the notion of bisimilarity. We first give an informal description of the game that we will employ. A match of the *bisimilarity game* between two Kripke models S and S' is played by two players,  $\exists$  and  $\forall$ . As in the evaluation game, these players move a token around from one *position* of the game to the next one. In the game there are two kinds of positions: pairs of the form  $(s, s') \in S \times S'$  are called *basic positions* and belong to  $\exists$ . The other positions are of the form  $Z \subseteq S \times S'$  and belong to  $\forall$ .

The idea of the game is that at a position (s, s'),  $\exists$  claims that s and s' are bisimilar, and to substantiate this claim she proposes a *local bisimulation*  $Z \subseteq S \times S'$  (see below) for s and s'. This relation Z can be seen as providing a set of *witnesses* for  $\exists$ 's claim that s and s' are bisimilar. Implicitly,  $\exists$ 's claim at a position  $Z \subseteq S \times S'$  is that *all* pairs in Z are bisimilar, so  $\forall$  can pick an arbitrary pair  $(t, t') \in Z$  and challenge  $\exists$  to show that these t and t' are bisimilar.

**Definition 1.25** Let S and S' be two transition systems of the same type (P, D). Then a relation  $Z \subseteq S \times S'$  is a *local bisimulation* for two points  $s \in S$  and  $s' \in S'$ , if it satisfies the properties (prop), (back) and (forth) of Definition 1.19 for this specific s and s': (prop)  $s \in V(p)$  iff  $s' \in V'(p)$ , for all  $p \in P$ ; (forth) for all actions d, and for all  $t \in R_d[s]$  there is a  $t' \in R_d[s']$  with  $(t, t') \in Z$ ; (back) for all actions d, and for all  $t' \in R'_d[s']$  there is a  $t \in R_d[s]$  with  $(t, t') \in Z$ .

Note that a local bisimulation for s and s' need only relate successors of s to successors of s'. In particular, the pair (s, s') itself will generally not belong to such a relation. It is easy to see that a relation Z between two Kripke models is a bisimulation iff Z is a local bisimulation for every pair  $(s, s') \in Z$ .

If a player gets stuck in a match of the bisimilarity game, then the opponent wins the match. For instance, if s and s' disagree about some proposition letter, then there is no local bisimulation for s and s', and so the corresponding position (s, s') is an immediate loss for  $\exists$ . Or, if neither s nor s' has successors, and agree on the truth of all proposition letters, then  $\exists$  could choose the *empty* relation as a local bisimulation, so that  $\forall$  would lose the match at his next move.

A new option arises if neither player gets stuck: this game may also have matches that last *forever*. Nevertheless, we can still declare a winner for such matches, and the agreement is that  $\exists$  is the winner of any infinite match. Formally, we put the following.

**Definition 1.26** The *bisimilarity game*  $\mathcal{B}(\mathbb{S}, \mathbb{S}')$  between two Kripke models  $\mathbb{S}$  and  $\mathbb{S}'$  is the board game given by Table 2, with the winning condition that finite matches are lost by the player who got stuck, while all infinite matches are won by  $\exists$ .

A position (s, s') is winning for  $\sigma$  if  $\sigma$  has a winning strategy for the game initialized in that position. The set of these positions is denoted as  $\operatorname{Win}_{\sigma}(\mathcal{B}(\mathbb{S}, \mathbb{S}'))$ .

Also observe that a bisimulation is a relation which is a local bisimulation for each of its members. The following theorem states that the collection of basic winning positions for  $\exists$  forms the *largest bisimulation* between S and S'.

Position	Player	Admissible moves			
$(s,s') \in S \times S'$	E	$\{Z \in \wp(S \times S') \mid Z \text{ is a local bisimulation for } s \text{ and } s'\}$			
$Z \in \wp(S \times S')$	$\forall$	$Z = \{(t, t') \mid (t, t') \in Z\}$			

#### Table 2: Bisimilarity game for Kripke models

**Theorem 1.27** Let  $(\mathbb{S}, s)$  and  $(\mathbb{S}', s')$  be two pointed Kripke models. Then  $\mathbb{S}, s \leftrightarrow \mathbb{S}', s'$  iff  $(s, s') \in Win_{\exists}(\mathcal{B}(\mathbb{S}, \mathbb{S}')).$ 

**Proof.** For the direction from left to right: suppose that Z is a bisimulation between S and S' linking s and s'. Suppose that  $\exists$ , starting from position (s, s'), always chooses the relation Z itself as the local bisimulation. A straightforward verification, by induction on the length of the match, shows that this strategy always provides her with a legitimate move, and that it keeps her alive forever. This proves that it is a winning strategy.

For the converse direction, it suffices to show that the relation  $\{(t, t') \in S \times S' \mid (t, t') \in Win_{\exists}(\mathcal{B}(\mathbb{S}, \mathbb{S}'))\}$  itself is in fact a bisimulation. We leave the details for the reader. QED

Remark 1.28 
The bisimilarity game should not be confused with the bisimulation game.

 $\triangleleft$ 

#### Bisimulations via relation lifting

Together, the back- and forth clause of the definition of a bisimulation express that the pair of respective successor sets of two bisimilar states must belong to the so-called *Egli-Milner* lifting  $\overline{\wp}Z$  of the bisimulation Z. In fact, the notion of a bisimulation can be completely defined in terms of relation lifting.

**Definition 1.29** Given a relation  $Z \subseteq A \times A'$ , define the relation  $\overline{\wp}Z \subseteq \wp A \times \wp A'$  as follows:

$$\overline{\wp}Z := \{ (X, X') \mid \text{ for all } x \in X \text{ there is an } x' \in X' \text{ with } (x, x') \in Z \\ \& \text{ for all } x' \in X' \text{ there is an } x \in X \text{ with } (x, x') \in Z \}$$

Similarly, define, for a Kripke functor  $\mathsf{K} = \mathsf{K}_{\mathsf{D},\mathsf{P}}$ , the relation  $\overline{\mathsf{K}}Z \subseteq \mathsf{K}A \times \mathsf{K}A'$  as follows:

$$\overline{\mathsf{K}}Z := \{ ((\pi, X), (\pi', X')) \mid \pi = \pi' \text{ and } (X_d, X'_d) \in \overline{\wp}Z \text{ for each } d \in \mathsf{D} \}.$$

The relations  $\overline{\wp}Z$  and  $\overline{\mathsf{K}}Z$  are called the *liftings* of Z with respect to  $\wp$  and  $\mathsf{K}$ , respectively. We say that  $Z \subseteq A \times A'$  is *full on*  $B \in \wp A$  and  $B' \in \wp A'$  if  $(B, B') \in \overline{\wp}Z$ .

It is completely straightforward to check that a nonempty relation Z linking two transition systems S and S' is a local bisimulation for two states s and s' iff  $(\sigma(s), \sigma'(s')) \in \overline{\mathsf{K}}Z$ . In particular,  $\exists$ 's move in the bisimilarity game at a position (s, s') consists of choosing a binary relation Z such that  $(\sigma(s), \sigma'(s')) \in \overline{\mathsf{K}}Z$ . The following characterization of bisimulations is also an immediate consequence. Lectures on the modal  $\mu$ -calculus

**Proposition 1.30** Let S and S' be two Kripke coalgebras for some Kripke functor K, and let  $Z \subseteq S \times S'$  be some relation. Then

Z is a bisimulation iff 
$$(\sigma(s), \sigma'(s')) \in \overline{\mathsf{K}}Z$$
 for all  $(s, s') \in Z$ . (1)

#### 1.7 The cover modality

As we will see now, there is an interesting alternative for the standard formulation of basic modal logic in terms of boxes and diamonds. This alternative set-up is based on a connective which turns a *set* of formulas into a formula. We first restrict attention to the monomodal case.

**Definition 1.31** Let  $\Phi$  be a finite set of formulas. Then  $\nabla \Phi$  is a formula, which holds at a state *s* in a Kripke model if *every* formula in  $\Phi$  holds at *some* successor of *s*, while at the same time, *every* successor of *s* makes *some* formula in  $\Phi$  true. The operator  $\nabla$  is called the *cover modality.* 

It is not so hard to see that the cover modality can be defined in the standard modal language:

$$\nabla \Phi \equiv \Box \bigvee \Phi \land \bigwedge \Diamond \Phi, \tag{2}$$

where  $\diamond \Phi$  denotes the set { $\diamond \varphi \mid \varphi \in \Phi$ }. Things start to get interesting once we realize that both the ordinary diamond  $\diamond$  and the ordinary box  $\Box$  can be expressed in terms of the cover modality (and the disjunction):

$$\begin{aligned} &\diamond \varphi &\equiv \nabla \{\varphi, \top \}, \\ &\Box \varphi &\equiv \nabla \emptyset \lor \nabla \{\varphi\}. \end{aligned}$$

$$(3)$$

Here, as always, we use the convention that  $\bigvee \emptyset = \bot$  and  $\bigwedge \emptyset = \top$ .

**Remark 1.32** Observe that this definition involves the  $\forall \exists \& \forall \exists$  pattern that we know from the definition of a bisimulation. The fundamental concept is the notion of *relation lifting*  $\overline{\wp}$  defined in the previous section. In other words, the semantics of the cover modality can be

expressed in terms of relation lifting. To be more precise, observe that we may think of the forcing or satisfaction relation  $\Vdash$  simply as a binary relation between states and formulas. Then we find that

$$\mathbb{S}, s \Vdash \nabla \Phi \text{ iff } (\sigma_R(s), \Phi) \in \overline{\wp}(\Vdash).$$

for any pointed Kripke model  $(\mathbb{S}, s)$  and any finite set  $\Phi$  of formulas.

**Remark 1.33** In the special case where  $\Phi = \emptyset$  we find that  $\mathbb{S}, s \Vdash \nabla \emptyset$  iff  $R[s] = \emptyset$ , that is, s has no successors. Using this it is easy to see that  $\top = \nabla \{\top\} \lor \nabla \emptyset$ .

Given that  $\nabla$  and  $\{\diamondsuit, \Box\}$  are mutually expressible, we obtain an expressively equivalent language  $ML_{\nabla}$  if we replace  $\Box$  and  $\diamondsuit$  with the cover modality. As we will see further on it will be convenient for us to use a format for this language in which not only the cover modality, but also the disjunction and conjunction connectives take finite sets of formulas as their argument. That is, rather then working with disjunction and conjunction as *binary* connectives, we will work with their *finitary* versions. This perspective also allows us to omit the constants  $\bot$  and  $\top$  from the basic syntax, since we may consider them as abbreviations:  $\bot := \bigvee \varnothing$  and  $\top := \bigwedge \varnothing$ .

**Definition 1.34** The formulas of the language  $ML_{\nabla}$  are given by the following grammar:

$$\varphi ::= p \mid \overline{p} \mid \bigvee \Phi \mid \land \Phi \mid \nabla \Phi$$

where p is a propositional variable, and  $\Phi \subseteq ML_{\nabla}$ .

**Proposition 1.35** The languages ML and  $ML_{\nabla}$  are equally expressive.

**Proof.** Immediate by (2) and (3).

The real importance of the cover modality is that it allows us to almost completely eliminate the Boolean *conjunction*. This remarkable fact is based on the following modal distributive law. Recall from Definition 1.29 that a relation  $Z \subseteq A \times A'$  is *full on* A and A' if  $(A, A') \in \overline{\wp}Z$ , or in other words:  $A \subseteq \text{Dom}(Z)$  and  $A' \subseteq \text{Ran}(Z)$ .

**Proposition 1.36 (Binary Modal Distributive Law)** Let  $\Phi$  and  $\Phi'$  be two sets of formulas. Then the following two formulas are equivalent:

$$\nabla \Phi \wedge \nabla \Phi' \equiv \bigvee \{ \nabla \Gamma_Z \mid Z \text{ is full on } \Phi \text{ and } \Phi' \}, \tag{4}$$

where, given a relation  $Z \subseteq \Phi \times \Phi'$ , we define

$$\Gamma_Z := \{ \varphi \land \varphi' \mid (\varphi, \varphi') \in Z \}.$$

**Proof.** For the direction from left to right, suppose that  $\mathbb{S}, s \Vdash \nabla \Phi \land \nabla \Phi'$ . Let  $Z \subseteq \Phi \times \Phi'$  consist of those pairs  $(\varphi, \varphi')$  such that the conjunction  $\varphi \land \varphi'$  is true at some successor t of s. It is then straightforward to verify that Z is full on  $\Phi$  and  $\Phi'$ , and that  $\mathbb{S}, s \Vdash \nabla \Gamma_Z$ .

The converse direction follows fairly directly from the definitions.

 $\triangleleft$ 

QED

QED

 $\triangleleft$ 

As a corollary of Proposition 1.36 we can restrict the use of conjunction in modal logic to that of a *special conjunction* connective  $\bullet$  which may only be applied to a pair consisting of a set of literals and a  $\nabla$ -formula (or, a certain set of  $\nabla$ -formulas in the polymodal case). The intended reading of the bullet operator is as follows:

$$\alpha \bullet \Phi \equiv (\bigwedge \alpha) \land \nabla \Phi.$$

**Definition 1.37** Fix a finite set P of proposition letters. Then the set DML(P) of *disjunctive* monomodal formulas in P is given by the following grammar:

$$\varphi ::= \top \mid \bigvee \Phi \mid \alpha \bullet \Phi,$$

where  $\alpha$  is a finite set of literals over P and  $\Phi$  is a finite set of formulas in DML(P).

Note that the proposition letters in P and their negations themselves do not qualify as disjunctive formulas. However, these formulas are easily seen to be equivalent to disjunctive formulas: for instance, we have  $\ell \equiv \{\ell\} \bullet \{\top\} \lor \{\ell\} \bullet \emptyset$ , for any literal  $\ell$ .

**Remark 1.38** In the above definition we do not need to list the formula  $\perp$  explicitly as a disjunctive formula, since we can see it as an abbreviation:  $\perp := \bigvee \emptyset$ . This is different for the formula  $\top$ , however. Since we no longer have  $\bigwedge$  as a connective, we cannot use it to define  $\top$ . For this reason we have added  $\top$  as a primitive constant.

The following theorem states that every modal formula can be rewritten into an equivalent disjunctive normal form.

**Theorem 1.39** Let P be a set of proposition letters. Then there are effective ways to transform an arbitrary formula in ML(P) into an equivalent formula in DML(P), and vice versa. As a corollary, the languages ML(P) and DML(P) are expressively equivalent.

We leave the proof of this result as an exercise to the reader.

**Remark 1.40** In the polymodal case we adapt the definition as follows. Let  $\Phi = \{\Phi_d \mid d \in D\}$  be a D-indexed family of formula sets. Then we write  $\nabla_D \Phi := \bigwedge_{d \in D} \nabla_d \Phi_d$ , where  $\nabla_d$  is the cover modality associated with the action d. The following grammar defines the set  $DML_D(P)$  of *disjunctive polymodal formulas* in D and P

$$\varphi ::= \top \mid \bigvee \Phi \mid \alpha \bullet \Phi,$$

where  $\alpha \subseteq_{\omega} \text{Lit}(\mathsf{P})$  and  $\Phi$  is an D-indexed family of finite sets of  $\text{DML}_{\mathsf{D}}(\mathsf{P})$ -formulas. One may then formulate and prove a polymodal version of Theorem 1.39, relating  $\text{ML}_{\mathsf{D}}$  and  $\text{DML}_{\mathsf{D}}$ .

#### Notes

Modal logic has a long history in philosophy and mathematics, for an overview we refer to Blackburn, de Rijke and Venema [3]. The use of modal formalisms as specification languages in process theory goes back at least to the 1970s, with Pratt [19] and Pnueli [18] being two influential early papers.

The notion of bisimulation, which plays an important role in modal logic and process theory alike, was first introduced in a modal logic context by van Benthem [2], who proved that modal logic is the bisimulation invariant fragment of first-order logic. The notion was later, but independently, introduced in a process theory setting by Park [17]. At the time of writing we do not know who first took a game-theoretical perspective on the semantics of modal logic. The cover modality  $\nabla$  was introduced independently by Moss [13] and Janin & Walukiewicz [7].

Readers who want to study modal logic in more detail are referred to Blackburn, de Rijke and Venema [3] or Chagrov & Zakharyaschev [5].

#### Exercises

Exercise 1.1 Prove Theorem 1.18.

**Exercise 1.2** Prove that the Hennessy-Milner theorem (Theorem 1.21) also holds if only one of the two structures is finitely branching.

**Exercise 1.3 (bisimilarity game)** Consider the following version  $\mathcal{B}_{\omega}(\mathbb{S}, \mathbb{S}')$  of the bisimilarity game between two transition systems  $\mathbb{S}$  and  $\mathbb{S}'$ . Positions of this game are of the form either  $(s, s', \forall, \alpha), (s, s', \exists, \alpha)$  or  $(Z, \alpha)$ , with  $s \in S, s' \in S', Z \subseteq S \times S'$  and  $\alpha$  either a natural number or  $\omega$ . The admissible moves for  $\exists$  and  $\forall$  are displayed in the following table:

Position	Player	Admissible moves	
$(s, s', \forall, \alpha)$	A	$\{(s, s', \exists, \beta) \mid \beta < \alpha\}$	
$(s, s', \exists, \alpha)$	E	$\{(Z, \alpha) \mid Z \text{ is a local bisimulation for } s \text{ and } s' \}$	
$(Z, \alpha)$	$\forall$	$\{(s,s',\forall,\alpha) \mid (s,s') \in Z\}$	

Note that all matches of this game have finite length.

We write  $\mathbb{S}, s \, \underline{\hookrightarrow}_{\alpha} \, \mathbb{S}', s'$  to denote that  $\exists$  has a winning strategy in the game  $\mathcal{B}_{\omega}(\mathbb{S}, \mathbb{S}')$ starting at position  $(s, s', \forall, \alpha)$ . It is not hard to see that  $\mathbb{S}, s \, \underline{\hookrightarrow}_{\omega} \, \mathbb{S}', s'$  iff  $\mathbb{S}, s \, \underline{\hookrightarrow}_k \, \mathbb{S}', s'$  for all  $k < \omega$ .

(a) Give concrete examples such that  $\mathbb{S}, s \leftrightarrow_{\omega} \mathbb{S}', s'$  but not  $\mathbb{S}, s \leftrightarrow \mathbb{S}', s'$ .

(Hint: think of two modally equivalent but not bisimilar states.)

(b) Let  $k \ge 0$  be a natural number. Prove that, for all  $\mathbb{S}$ , s and  $\mathbb{S}'$ , s':

$$\mathbb{S}, s \leftrightarrow_k \mathbb{S}', s' \Rightarrow \mathbb{S}, s \equiv_k \mathbb{S}', s'$$

Here  $\equiv_k$  denotes the modal equivalence relation with respect to formulas of modal depth at most k. Here we use a slightly nonstandard notion of modal depth, defined as follows:  $d(\perp), d(\top) := 0, d(p), d(\overline{p}) := 1$  for  $p \in \mathsf{P}, d(\varphi \land \psi), d(\varphi \lor \psi) := \max(d(\varphi), d(\psi))$ , and  $d(\diamond \varphi), d(\Box \varphi) := 1 + d(\varphi)$ .

Lectures on the modal  $\mu$ -calculus

- (c) Let S and S' be finitely branching transition systems. Prove *directly* (i.e., without using part (b)) that (i)  $\Rightarrow$  (ii), for all  $s \in S$  and  $s' \in S'$ :
  - (i)  $\mathbb{S}, s \nleftrightarrow_{\omega} \mathbb{S}', s'$
  - (ii)  $\mathbb{S}, s \leftrightarrow \mathbb{S}', s'$ .
- (d)\* Does the implication in (c) hold in the case that only *one* of the two transition systems is finitely branching?

**Exercise 1.4** Let  $\Phi$  and  $\Theta$  be finite sets of formulas. Prove that

$$\nabla \big( \Phi \cup \{ \bigvee \Theta \} \big) \; \equiv \; \bigvee \big\{ \nabla \big( \Phi \cup \Theta' \big) \; \mid \; \varnothing \neq \Theta' \subseteq \Theta \big\}.$$

Exercise 1.5 Prove Theorem 1.39.

## 2 The modal $\mu$ -calculus: basics

This chapter is a first introduction to the modal  $\mu$ -calculus. We define the language, discuss some syntactic issues, and then proceed to its game-theoretic semantics, in two variants. As a first result, we prove that the modal  $\mu$ -calculus is bisimulation invariant, and has a strong, 'bounded' version of the tree model property. We then provide some basic information concerning the main complexity measures of  $\mu$ -calculus formulas: size and alternation depth, and we discuss some further syntactic issues.

To introduce the formalism, we start with a simple example.

**Example 2.1** Consider the formula  $\langle d^* \rangle p$  from propositional dynamic logic. By definition, this formula holds at those points in an LTS S from which there is a finite  $R_d$ -path, of unspecified length, leading to a state where p is true.

We leave it for the reader to prove that

$$\mathbb{S}, s \Vdash \langle d^* \rangle p \leftrightarrow (p \lor \langle d \rangle \langle d^* \rangle p)$$

for any pointed transition system  $(\mathbb{S}, s)$  (here we write  $\langle d \rangle$  rather than  $\diamond_d$ ). Informally, one might say that  $\langle d^* \rangle p$  is a *fixed point* of the formula  $p \vee \langle d \rangle x$ , or a solution of the 'equation'

$$x \equiv p \lor \langle d \rangle x. \tag{5}$$

One may show, however, that  $\langle d^* \rangle p$  is not the only fixpoint of (5). If we let  $\infty_d$  denote a formula that is true at those states of a transition system from which an infinite *d*-path emanates, then the formula  $\langle d^* \rangle p \vee \infty_d$  is another fixed point of (5).

In fact, one may prove that the two mentioned fixpoints are the smallest and largest possible solutions of (5), respectively.  $\triangleleft$ 

The modal  $\mu$ -calculus allows one to explicitly refer to such smallest and largest solutions. For instance, the smallest and largest solution of the 'equation' (5) will be written as  $\mu x.p \lor \langle d \rangle x$  and  $\nu x.p \lor \langle d \rangle x$ , respectively. The basic idea underlying the modal  $\mu$ -calculus is to enrich the language of basic modal logic with two explicit fixpoint operators,  $\mu$  and  $\nu$ , respectively. Syntactically, these operators behave like quantifiers in first-order logic, in the sense that the application of a fixpoint operator  $\mu x$  to a formula  $\varphi$  binds all (free) occurrences of the proposition letter x in  $\varphi$ . The word 'fixpoint' indicates that semantically, the formulas  $\mu x \varphi$  and  $\nu x \varphi$  are both 'solutions' to the 'equation'  $x \equiv \varphi(x)$ , in the sense that, writing  $\equiv$  for semantic equivalence, we have both

$$\begin{array}{rcl}
\mu x \,\varphi &\equiv & \varphi[\mu x \,\varphi/x] \\
\text{and} & \nu x \,\varphi &\equiv & \varphi[\nu x \,\varphi/x],
\end{array}$$
(6)

where  $[\mu x.\varphi/x]$  denotes the operation of substituting  $\mu x \varphi$  for every free occurrence of x. In other words, both  $\mu x \varphi$  and  $\nu x \varphi$  are equivalent to their respective unfoldings,  $\varphi[\mu x \varphi/x]$  and  $\varphi[\nu x \varphi/x]$ .

To arrive at this semantics of modal fixpoint formulas one can take two roads. In Chapter 3 we will introduce the algebraic semantics of  $\mu x \varphi$  and  $\nu x \varphi$  in an LTS S, in terms of the

*least* and *greatest fixpoint*, respectively, of some algebraically defined meaning function. For this purpose, we will interpret the formula  $\varphi(x)$  as an operation  $\varphi_x^{\mathbb{S}}$  on the power set of (the state space of)  $\mathbb{S}$ , and we have to prove that this operation indeed has a least and a greatest fixpoint. This formal definition of the semantics of the modal  $\mu$ -calculus may be mathematically transparent, but it is of little help when it comes to unravelling and understanding the actual meaning of individual formulas. In practice, it is much easier to work with the *evaluation games* that we will introduce in this chapter.

This framework builds on the game-theoretical semantics for ordinary modal logic as described in Subsection 1.2, extending it with features for the fixpoint operators and for the bound variables of fixpoint formulas (such as x in the formula  $\mu x.p \lor \diamond x$ ). The key difference lies in the fact that when a match of the subformula-based evaluation game reaches a position of the form (x, s), with x a bound variable, then an equation such as (5) is used to unfold the variable x into its associated formula  $\delta$  (in the example, the formula  $p \lor \diamond x$ ), so that the next position in the game is the pair  $(\delta, s)$ . The alternative version of the evaluation game also crucially involves unfolding: here, for instance, a position of the form  $(\mu x \varphi, s)$  is replaced by the pair  $(\varphi[\mu x \varphi/x], s)$  we obtain by unfolding the fixpoint formula  $\mu x \varphi$ .

As a consequence, the flavour of these games is remarkably different from the evaluation games we met before. Recall that in evaluation matches for *basic* modal formulas, the formula is broken down, step by step, until we can declare a winner of the match. From this it follows that the length of such a match is *bounded* by the length of the formula. Evaluation matches for fixpoint formulas, on the other hand, can last forever, if some fixpoint variables or fixpoint formulas are unfolded infinitely often. Hence, the game-theoretic semantics for fixpoint logics takes us to the area of *infinite games*. In this Chapter we keep our treatment of infinite games informal, in Chapter 5 the reader can find precise definitions of all notions that we introduce here.

#### 2.1 Basic syntax

#### Formulas

As announced already in the previous chapter, in the case of fixpoint formulas we will usually work with formulas in *positive normal form* in which the only admissible occurrences of the negation symbol is in front of atomic formulas.

**Definition 2.2** Given a set D of atomic actions, we define the collection  $\mu$ ML<sub>D</sub> of (*poly-*)modal fixpoint formulas as follows:

 $\varphi ::= \top \mid \perp \mid p \mid \overline{p} \mid (\varphi \land \varphi) \mid (\varphi \lor \varphi) \mid \diamond_{d} \varphi \mid \Box_{d} \varphi \mid \mu x \varphi \mid \nu x \varphi$ 

where p and x are propositional variables, and  $d \in D$ . There is a restriction on the formation of the formulas  $\mu x \varphi$  and  $\nu x \varphi$ , namely, that the formula  $\varphi$  is *positive* in x. That is, all occurrences of x in  $\varphi$  are *positive*, or, phrasing it yet differently, no occurrence of x in  $\varphi$  may be in the form of the negative literal  $\overline{x}$ .

In case the set D of atomic actions is a singleton, we will simply speak of the *modal*  $\mu$ -calculus, notation:  $\mu$ ML.

The syntactic combinations  $\mu x$  and  $\nu x$  are called the *least* and *greatest fixpoint operators*, respectively. We use the symbols  $\eta$  and  $\lambda$  to denote either  $\mu$  or  $\nu$ , and we define  $\overline{\mu} := \nu$  and  $\overline{\nu} := \mu$ .

A formula of the form  $\eta x \varphi$  is called a *fixpoint formula*, and, more specifically, a  $\mu$ -formula if  $\eta = \mu$  and a  $\nu$ -formula if  $\eta = \nu$ . Furthermore, conjunctions and disjunctions will sometimes be called *boolean*  $\mu$ ML-formulas, and formulas of the form  $\diamondsuit_d \varphi$  or  $\Box_d$  will sometimes be called *modal*.

**Convention 2.3** In order to increase readability by reducing the number of brackets, we adopt some standard scope conventions. We let the unary modal connectives,  $\diamond$  and  $\Box$ , bind stronger than the binary propositional connectives  $\land$ ,  $\lor$  and  $\rightarrow$ , and use associativity to the left for the connectives  $\land$  and  $\lor$ . As an example, we will abbreviate the formula ( $\diamond p \land q$ ) as  $\diamond p \land q$ .

Furthermore, we use 'dot notation' to indicate that the fixpoint operators preceding the dot have maximal scope. For instance,  $\mu p.\Diamond p \land q$  denotes the formula  $\mu p(\Diamond p \land q)$ , and not the formula  $((\mu p \Diamond p) \land q)$ . As a final example,  $\mu x.\overline{p} \lor \Box x \lor y \lor \nu y.q \land \Box (x \lor y)$  stands for  $\mu x \left( ((\overline{p} \lor \Box x) \lor y) \lor \nu y (q \land \Box (x \lor y)) \right)$ .

**Remark 2.4** An alternative definition of the language of the modal  $\mu$ -calculus makes a distinction between propositional *variables* and *proposition letters*. Formulas are now defined as follows:

 $\varphi \, ::= \, \top \, \mid \, \perp \, \mid \, p \, \mid \, \overline{p} \, \mid \, x \, \mid \, (\varphi \wedge \varphi) \, \mid \, (\varphi \vee \varphi) \, \mid \, \diamondsuit_d \varphi \, \mid \, \Box_d \varphi \, \mid \, \mu x \, \varphi \, \mid \, \nu x \, \varphi$ 

where p is a proposition letter, x a propositional variable, and d is an atomic action. In this framework, only propositional variables can be bound.

#### Length and syntax tree of a formula

There are various ways to *measure* a  $\mu$ -calculus formula. The most basic measure of a formula is its *length*, which basically corresponds to its number of symbols.

**Definition 2.5** Given a  $\mu$ -calculus formula  $\xi$ , we define its *length*  $|\xi|^{\ell}$  inductively as follows:

$ arphi ^\ell$	:=	1	if $\varphi$ is atomic
	:=	$1+ \varphi_0 ^\ell+ \varphi_1 ^\ell$	where $\circledast \in \{\land, \lor\}$
$ \nabla \varphi ^{\ell}$	:=	$1+ \varphi ^{\ell}$	where $\heartsuit \in \{\diamondsuit, \square\}$
$ \eta x. \varphi ^{\ell}$	:=	$1+ \varphi ^{\ell}$	where $\eta \in \{\mu, \nu\}$

We assume that the reader is familiar with the concept of the syntax tree or construction tree  $\mathbb{T}_{\xi}$  of a formula  $\xi$ . We will not give a formal definition of this structure, but confine ourselves to an example: in Figure 2.1 we display the syntax tree of the  $\mu$ -calculus formula  $\mu x.(\bar{p} \lor \diamondsuit x) \lor \nu y.(q \land \Box(x \lor y))$ . Note that the *length* of a formula corresponds to the number of nodes of its syntax tree, and that an *occurrence* of a certain symbol in a formula may be associated with some node in the formula's syntax tree that is labelled with that symbol; occurrences of literals correspond to *leaves* of the tree.

 $\triangleleft$ 

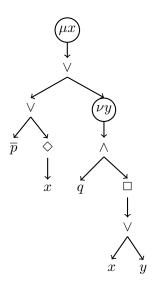

Figure 1: A syntax tree

#### Subformulas and free/bound variables

The concepts of *subformula* and *proper subformula* are extended from basic modal logic to the modal  $\mu$ -calculus in the obvious way.

**Definition 2.6** We define the set  $Sf_0(\xi)$  of *direct subformulas* of a formula  $\xi \in \mu ML$  via the following case distinction:

$Sf_0(\xi)$	:=	Ø	$\text{if } \xi \in \texttt{At}(P)$
$Sf_0(\xi_0 \circledast \xi_1)$	:=	$\{\xi_0,\xi_1\}$	where $\circledast \in \{\land, \lor\}$
$Sf_0(\heartsuit \xi_0)$	:=	$\{\xi_0\}$	where $\heartsuit \in \{\diamondsuit, \square\}$
$Sf_0(\eta x.\xi_0)$	:=	$\{\xi_0\}$	where $\eta \in \{\mu, \nu\}$ ,

and we write  $\varphi \triangleleft_0 \xi$  if  $\varphi \in Sf_0(\xi)$ .

For any formula  $\xi \in \mu ML$ ,  $Sf(\xi)$  is the least set of formulas which contains  $\xi$  and is closed under taking direct subformulas. Elements of the set  $Sf(\xi)$  are called *subformulas* of  $\xi$ , and we write  $\varphi \leq \xi$  ( $\varphi \leq \xi$ ) if  $\varphi$  is a subformula (proper subformula, respectively) of  $\xi$ .

The *(subformula)* dag of a formula  $\xi$  is defined as the directed acyclic graph  $(Sf(\xi), \triangleright_0)$ , where  $\triangleright_0$  is the converse of the direct subformula relation  $\triangleleft_0$ .

#### ▶ Give an example comparing the syntax tree of a formula to its subformula dag.

Syntactically, the fixpoint operators are very similar to the quantifiers of first-order logic in the way they *bind* variables.

**Definition 2.7** Fix a formula  $\varphi$ . The sets  $FV(\varphi)$  and  $BV(\varphi)$  of free and bound variables of  $\varphi$  are defined by the following induction on  $\varphi$ :

$FV(\perp)$	:=	Ø	$BV(\perp)$	:=	Ø
$FV(\top)$	:=	Ø	$BV(\top)$	:=	Ø
FV(p)	:=	$\{p\}$	BV(p)	:=	Ø
$FV(\overline{p})$	:=	$\{p\}$	$BV(\overline{p})$	:=	Ø
$FV(\varphi \lor \psi)$	:=	$FV(\varphi) \cup FV(\psi)$	$BV(\varphi \lor \psi)$	:=	$BV(\varphi) \cup BV(\psi)$
$FV(\varphi \wedge \psi)$	:=	$FV(\varphi) \cup FV(\psi)$	$BV(\varphi \wedge \psi)$	:=	$BV(\varphi) \cup BV(\psi)$
$FV(\diamondsuit_d \varphi)$	:=	FV(arphi)	$BV(\diamondsuit_d \varphi)$	:=	BV(arphi)
$FV(\Box_d \varphi)$	:=	FV(arphi)	$BV(\Box_d\varphi)$	:=	BV(arphi)
$FV(\eta x.\varphi)$	:=	$FV(\varphi) \setminus \{x\}$	$BV(\eta x.\varphi)$	:=	$BV(\varphi) \cup \{x\}$

For a finite set of propositional variables P, we let  $\mu ML_D(P)$  denote the set of  $\mu ML_D$ -formulas  $\varphi$  of which all free variables belong to P.

Formulas like  $x \lor \mu x.((p \lor x) \land \Box \nu x. \diamondsuit x)$  may be well formed, but in practice they are very hard to read and to work with. In the sequel we will often work with formulas in which every bound variable uniquely determines a subformula where it is bound, and almost exclusively with formulas in which no variable has both free and bound occurrences in  $\varphi$ .

**Definition 2.8** A formula  $\varphi \in \mu ML_D$  is *tidy* if  $FV(\varphi) \cap BV(\varphi) = \emptyset$ , and *clean* if in addition with every bound variable x of  $\varphi$  we may associate a unique subformula of the form  $\eta x.\delta$ . In the latter case we let  $\varphi_x = \eta_x x.\delta_x$  denote this unique subformula.

**Convention 2.9** As a notational convention, we will use the letters  $p, q, r, \ldots$  and  $x, y, z, \ldots$  to denote, respectively, the free and the bound propositional variables of a  $\mu$ ML<sub>D</sub>-formula. This convention can be no more than a guideline, since the division between bound and free variables may not be the same for a formula and its subformulas. For instance, the variable x is bound in  $\mu x.p \lor \Diamond x$ , but free in its subformula  $p \lor \Diamond x$ .

**Remark 2.10** In the alternative definition of the language of the modal  $\mu$ -calculus as discussed in Remark 2.4, just like in first-order logic one makes a difference between *(open)* formulas (which may contain free variables) and sentences (which may not). Observe that the sentences correspond to the tidy formulas in our framework. For instance,  $\mu x (p \lor \Diamond x)$  is a sentence,  $\mu x (y \lor \Diamond x)$  is an open formula, and  $\mu p (x \lor \Diamond p)$  is not a well-formed formula (assuming that p is a proposition letter, and x is a variable).

#### Substitution

The syntactic operation of substitution is ubiquitous in any account of the modal  $\mu$ -calculus, first of all because it features in the basic operation of unfolding a fixpoint formula. As usual in the context of a formal language featuring operators that *bind* variables, the precise definition of a substitution operation needs some care. In particular, we need to protect the substitution operation from variable capture.

**Example 2.11** To give a concrete example, suppose that we would naively define a substitution operation  $\psi/x$  by defining  $\varphi[\psi/x]$  to be the formula we obtain from the formula  $\varphi$  by replacing every free occurrences of x with the formula  $\psi$ . Now consider the formula  $\varphi(q) = \mu p.q \lor \Diamond p$  expressing the reachability of a q-state in finitely many steps. If we substitute p for q in  $\varphi$ , we would expect the resulting formula to express the reachability of a p-state in finitely many steps, but the formula we obtain is  $\varphi[p/q] = \mu p.p \lor \Diamond p$ , which says something rather different (in fact, it happens to be equivalent to  $\bot$ ). Even worse, the substitution  $[\overline{p}/q]$  would produce a syntactic string  $\varphi[\overline{p}/q] = \mu p.\overline{p} \lor \Diamond p$  which is not even a well-formed formula.

To avoid such anomalies, for the time being we shall only consider substitutions  $\xi/x$  applied to formulas where  $\xi$  is free for x.

**Definition 2.12** Let  $\xi$  and x be respectively a modal  $\mu$ -calculus formula and a propositional variable. We define what it means for  $\xi$  to be *free for* x *in a formula*  $\varphi$  by the following induction on the complexity of  $\varphi$ :

- if  $\varphi$  is an atomic formula then  $\xi$  is free for x in  $\varphi$ , unless  $\varphi = \overline{x}^1$ ;
- $\xi$  is free for x in  $\varphi_0 \circledast \varphi_1$  if it is free for x in both  $\varphi_0$  and  $\varphi_1$ ;
- $\xi$  is free for x in  $\heartsuit \psi$  if it is free for x in  $\psi$ ;
- $\xi$  is free for x in  $\eta y \psi$  if  $x \notin FV(\eta y \psi)$  or if  $y \notin FV(\xi)$  and  $\xi$  is free for x in  $\psi$ .

Informally,  $\xi$  is *free for* x *in*  $\varphi$  if  $\varphi$  is positive in x and no free variable in  $\xi$  gets bound, after substitution, by a fixpoint operator in  $\varphi$ . A special case of this, that we shall encounter frequently, is the following.

**Proposition 2.13** Let  $\varphi, \xi$  and x be respectively two modal  $\mu$ -calculus formulas and a propositional variable, such that  $FV(\xi) \cap BV(\varphi) \subseteq \{x\}$ . Then  $\xi$  is free for x in  $\varphi$ .

**Definition 2.14** Let  $\{\xi_z \mid z \in Z\}$  be a set of modal  $\mu$ -calculus formulas, indexed by a set of variables Z, let  $\varphi \in \mu ML$  be positive in each  $z \in Z$ , and assume that each  $\xi_z$  is free for z in  $\varphi$ . We inductively define the *simultaneous substitution*  $[\xi_z/z \mid z \in Z]$  as the following operation on  $\mu ML$ :

$\varphi[\xi_z/z \mid z \in Z]$	:=	$\begin{cases} \xi_z & \text{if } \varphi = z \in Z \\ \varphi & \text{if } \varphi \text{ is atomic but } \varphi \notin Z \end{cases}$
$(\heartsuit\psi)[\xi_z/z \mid z \in Z]$	:=	$\heartsuit\psi[\xi_z/z \mid z \in Z]$
$(\varphi_0 \circledast \varphi_1)[\xi_z/z \mid z \in Z]$	:=	$\varphi_0[\xi_z/z \mid z \in Z] \circledast \varphi_1[\xi_z/z \mid z \in Z]$
$(\eta x.\psi)[\xi_z/z \mid z \in Z]$	:=	$\eta x.\psi[\xi_z/z \mid z \in Z \setminus \{x\}]$

In case Z is a singleton, say  $Z = \{z\}$ , we will simply write  $\varphi[\xi_z/z]$ , or  $\varphi(\xi)$  if z is understood.  $\triangleleft$ 

<sup>&</sup>lt;sup>1</sup>Strictly speaking, this condition is not needed. In particular, as a separate atomic case of our inductive definition, we could define the outcome of the substitution  $\overline{p}[\psi/p]$  to be the *negation* of the formula  $\psi$  (suitably defined). However, we will only need to look at substitutions  $\varphi[\psi/z]$  where we happen to know that  $\varphi$  is positive in z. As a result, our simplified definition does not impose a real restriction.

Lectures on the modal  $\mu$ -calculus

#### ▶ Add some examples

**Remark 2.15** In case  $\psi$  is not free for some  $z \in Z$  in  $\xi$ , we take a standard approach using *alphabetical variants*. Roughly, two formulas are alphabetical variants if we can obtain one from the other by renaming bound variables. We then define a correct version of the substitution  $\xi[\psi_z/z \mid z \in Z]$  as follows: first we take some canonically chosen alphabetical variant  $\xi'$  of  $\xi$  such that each  $\psi_z$  is free for z in  $\xi'$ , and then we set

$$\xi[\psi_z/z \mid z \in Z] := \xi'[\psi_z/z \mid z \in Z].$$

However, in almost all situations that we will encounter we will only need perform substitutions that are 'safe' in the sense that the substituted formula is free for the variable it replaces. This means that generally we may avoid taking alphabetical variants. Situations where this is not the case will be explicitly marked. The reason for taking such care is that the operation of taking alphabetical variants is not completely harmless when it comes to size issues. We will come back to this matter in more detail later.  $\triangleleft$ 

#### Unfolding

The reason that the modal  $\mu$ -calculus, and related formalisms, are called *fixpoint logics* is that, for  $\eta = \mu/\nu$ , the meaning of the formula  $\eta x.\chi$  in a model S is given as the least/greatest *fixpoint* of the semantic map expressing the dependence of the meaning of  $\chi$  on (the meaning of) the variable x. As a consequence, the following equivalence lies at the heart of semantics of  $\mu$ ML:

$$\eta x. \chi \equiv \chi [\eta x. \chi/x] \tag{7}$$

In words: every formula is equivalent to its *unfolding*.

**Definition 2.16** Given a formula  $\eta x. \chi \in \mu ML$ , we call the formula  $unf(\xi) := \chi[\eta x. \chi/x]$  its *unfolding*.

**Remark 2.17** Unfolding is the central operation in taking the closure of a formula that we are about to define. Unfortunately, the collection of clean formulas is not closed under unfolding (unless we take alphabetical variants). Consider for instance the formula  $\varphi(p) = \nu q. \Diamond q \land p$ , then we see that the formula  $\mu p.\varphi$  is clean, but its unfolding  $\varphi[\mu p.\varphi/p] = \nu q. \Diamond q \land \mu p \nu q. \Diamond q \land p$ is not. Furthermore, our earlier observation that the naive version of substitution may produce 'formulas' that are not well formed applies here as well. For instance, with  $\chi$  denoting the formula  $\overline{p} \land \nu p. \Box(x \lor p)$ , naively unfolding the (untidy) formula  $\mu x.\chi$  would produce the ungrammatical  $\overline{p} \land \nu p. \Box((\mu x. \overline{p} \land \nu p. \Box(x \lor p)) \lor p)$ .

Fortunately, the condition of *tidyness* guarantees that we may calculate unfoldings without moving to alphabetical variants, since we can prove that the formula  $\eta x.\chi$  is free for x in  $\chi$ , whenever  $\eta x.\chi$  is tidy. In addition, tidyness is preserved under taking unfoldings.

**Proposition 2.18** Let  $\eta x. \chi \in \mu ML$  be a tidy formula. Then 1)  $\eta x. \chi$  is free for x in  $\chi$ ; 2)  $\chi[\eta x.\chi/x]$  is tidy as well.

**Proof.** For part 1), take a variable  $y \in FV(\eta x.\chi)$ . Then obviously y is distinct from x, while  $y \notin BV(\eta x.\chi)$  by tidyness. Clearly then we find  $y \notin BV(\chi)$ ; in other words,  $\chi$  has no subformula of the form  $\lambda y.\psi$ . Hence it trivially follows that  $\eta x.\chi$  is free for x in  $\chi$ .

Part 2) is immediate by the following identities:

$$FV(\chi[\eta x.\chi/x]) = (FV(\chi) \setminus \{x\}) \cup FV(\eta x.\chi) = FV(\eta x.\chi)$$
  

$$BV(\chi[\eta x.\chi/x]) = BV(\chi) \cup BV(\eta x.\chi) = BV(\eta x.\chi)$$

which can easily be proved.

#### Guardedness

We continue our discussion of basic syntactic definitions with the notion of guardedness, which will become important later on.

▶ A bit more to be said here.

**Definition 2.19** A variable x is guarded in a  $\mu$ ML<sub>D</sub>-formula  $\varphi$  if every free occurrence of x in  $\varphi$  is in the scope of a modal operator. A formula  $\xi \in \mu$ ML<sub>D</sub> is guarded if for every subformula of  $\xi$  of the form  $\eta x.\delta$ , x is guarded in  $\delta$ .

In the next chapter we will prove that every formula can be effectively rewritten into an equivalent guarded formula.

#### 2.2 The evaluation game based on subformulas

For a definition of the evaluation game of the modal  $\mu$ -calculus, fix a *clean* formula  $\xi$  and an LTS S. Basically, the game  $\mathcal{E}(\xi, S)$  for  $\xi$  a fixpoint formula is defined in the same way as for plain modal logic formulas.

**Definition 2.20** Given a clean modal  $\mu$ -calculus formula  $\xi$  and a transition system  $\mathbb{S}$ , we define the *evaluation game* or *model checking game*  $\mathcal{E}(\xi, \mathbb{S})$  as a board game with players  $\exists$  and  $\forall$  moving a token around positions of the form  $(\varphi, s) \in Sf(\xi) \times S$ . The rules, determining the admissible moves from a given position, together with the player who is supposed to make this move, are given in Table 3.

As before,  $\mathcal{E}(\xi, \mathbb{S})@(\xi, s)$  denotes the instantiation of this game where the starting position is fixed as  $(\xi, s)$ .

One might expect that the main difference with the evaluation game for basic modal formulas would involve the new formula constructors of the  $\mu$ -calculus: the fixpoint operators. Perhaps surprisingly, we can deal with the fixpoint operators themselves in the most straightforward way possible, viz., by simply *stripping* them. That is, the successor of a position of the form  $(\eta x.\delta, s)$  is simply obtained as the pair  $(\delta, s)$ . (In section 2.5 we present an alternative version in which the formula  $\eta x \delta$  is replaced with its unfolding). Since this next position is thus uniquely determined, the position  $(\eta x.\delta, s)$  will not be assigned to either of the players.

QED

The crucial difference lies in the treatment of the *bound variables* of a fixpoint formula  $\xi$ . Previously, all positions of the form (p, s) would be *final positions* of the game, immediately determining the winner of the match, and this is still the case here if p is a *free* variable. However, at a position (x, s) with x bound, the fixpoint variable x gets unfolded; this means that the new position is given as  $(\delta_x, s)$ , where  $\eta_x x \cdot \delta_x$  is the unique subformula of  $\xi$  where x is bound. Note that for this to be well defined, we need  $\xi$  to be clean. The disjointness of  $FV(\xi)$  and  $BV(\xi)$  ensures that it is always clear whether a variable is to be unfolded or not, and the fact that bound variables are bound by unique occurrences of fixpoint operators guarantees that  $\delta_x$  is uniquely determined. Finally, since in this case the next position is also completely determined by the current one, positions of the form (x, s) with x bound are assigned to neither of the players.

Position	Player	Admissible moves
$(\varphi_1 \lor \varphi_2, s)$	Ξ	$\{(\varphi_1, s), (\varphi_2, s)\}$
$(\varphi_1 \land \varphi_2, s)$	$\forall$	$\{(\varphi_1, s), (\varphi_2, s)\}$
$(\diamondsuit_d \varphi, s)$	Ξ	$\{(\varphi, t) \mid t \in \sigma_d(s)\}$
$(\Box_d \varphi, s)$	$\forall$	$\{(\varphi, t) \mid t \in \sigma_d(s)\}$
$(\perp,s)$	E	Ø
$(\top, s)$	$\forall$	Ø
$(p, s)$ , with $p \in FV(\xi)$ and $s \in V(p)$	$\forall$	Ø
$(p, s)$ , with $p \in FV(\xi)$ and $s \notin V(p)$	E	Ø
$(\overline{p}, s)$ , with $p \in FV(\xi)$ and $s \in V(p)$	Э	Ø
$(\overline{p}, s)$ , with $p \in FV(\xi)$ and $s \notin V(p)$	$\forall$	Ø
$(\eta_x x.\delta_x,s)$	_	$\{(\delta_x,s)\}$
$(x,s)$ , with $x \in BV(\xi)$	_	$\{(\delta_x,s)\}$

Table 3: Evaluation game for clean modal fixpoint logic

**Example 2.21** Let  $\mathbb{S} = \langle S, R, V \rangle$  be the Kripke model based on the set  $S = \{0, 1, 2\}$ , with  $R = \{(0, 1), (1, 1), (1, 2), (2, 2)\}$ , and V given by  $V(p) = \{2\}$ . Now let  $\xi$  be the formula  $\eta x.p \vee \Box x$ , and consider the game  $\mathcal{E}(\xi, \mathbb{S})$  initialized at  $(\xi, 0)$ .

The second position of any match of this game will be  $(p \vee \Box x, 0)$  belonging to  $\exists$ . Assuming that she wants to win, she chooses the disjunct  $\Box x$  since otherwise p being false at 0 would mean an immediate loss for her. Now the position  $(\Box x, 0)$  belongs to  $\forall$  and he will make the only move allowed to him, choosing (x, 1) as the next position. Here an automatic move is made, *unfolding* the variable x, and thus changing the position to  $(p \vee \Box x, 1)$ . And as before,  $\exists$  will choose the right disjunct:  $(\Box x, 1)$ .

At  $(\Box x, 1)$ ,  $\forall$  does have a choice. Choosing (x, 2), however, would mean that  $\exists$  wins the match since p being true at 2 enables her to finally choose the first disjunct of the formula  $p \lor \Box x$ . So  $\forall$  chooses (x, 1), a position already visited by the match before.

This means that these strategies force the match to be *infinite*, with the variable x unfolding infinitely often at positions of the form (x, 1), and the match taking the following

form:

$$(\xi, 0)(p \lor \Box x, 0)(\Box x, 0)(x, 1)(p \lor \Box x, 1)(\Box x, 1)(x, 1)(p \lor \Box x, 1)\dots$$

So who is declared to be the winner of this match? This is where the difference between the two fixpoint operators shows up. In case  $\eta = \mu$ , the above infinite match is *lost* by  $\exists$  since the fixpoint variable that is unfolded infinitely often is a  $\mu$ -variable, and  $\mu$ -variables are to be unfolded only finitely often. In case  $\eta = \nu$ , the variable unfolded infinitely often is a  $\nu$ -variable, and this is unproblematic:  $\exists$  wins the match.

The above example shows the principle of unfolding at work. Its effect is that matches may now be of infinite length since formulas are no longer deconstructed at every move of the game. Nevertheless, as we will see, it will still be very useful to declare a *winner* of such an infinite game. Here we arrive at one of the key ideas underlying the semantics of fixpoint formulas, which in a slogan can be formulated as follows:

 $\nu$  means unfolding,  $\mu$  means finite unfolding.

Giving a more detailed interpretation to this slogan, in case of a unique variable that is unfolded infinitely often during a match  $\pi$ , we will declare  $\exists$  to be the winner of  $\pi$  if this variable is a  $\nu$ -variable, and  $\forall$  in case we are dealing with a  $\mu$ -variable. But what happens in case that *various* variables are unfolded infinitely often?

**Definition 2.22** Let  $\xi$  be a clean  $\mu$ ML<sub>D</sub>-formula, and S a labelled transition system. A *match* of the game  $\mathcal{E}(\xi, S)$  is a (finite or infinite) sequence of positions

$$\pi = (\varphi_i, s_i)_{i < \kappa}$$

(where  $\kappa$  is either a natural number or  $\omega$ ) which is in accordance with the rules of the evaluation game — that is,  $\pi$  is a path through the game graph given by the admissibility relation of Table 3. A *full match* is either an infinite match, or a finite match in which the player responsible for the last position got stuck. In practice we will always refer to full matches simply as *matches*. A match that is not full is called *partial*.

Given an infinite match  $\pi$ , we let  $Unf^{\infty}(\pi) \subseteq BV(\xi)$  denote the set of variables that are unfolded infinitely often during  $\pi$ .

As we will see now, for any infinite match  $\pi$  of the evaluation game, the set  $Unf^{\infty}(\pi)$  contains a unique variable that ranks higher than all the others in the following order.

**Definition 2.23** Given a clean formula  $\xi$ , we define the *unfolding order*  $\leq_{\xi}$  on the set  $BV(\xi)$  by putting  $x \leq_{\xi} y$  if  $\delta_x \leq \delta_y$ . If  $x \leq_{\xi} y$  we say that y ranks at least as high as x.

**Proposition 2.24** Let  $\xi$  be a clean  $\mu$ ML<sub>D</sub>-formula, and  $\mathbb{S}$  a labelled transition system. Then for any infinite match  $\pi$  of the game  $\mathcal{E}(\xi, \mathbb{S})$ , the set  $Unf^{\infty}(\pi)$  has a highest ranking member, in terms of the unfolding order  $\leq_{\xi}$ .

**Proof.** Since  $\pi$  is an infinite match, the set  $U := Unf^{\infty}(\pi)$  is not empty. Let y be an element of U which is *maximal* (with respect to the ranking order  $\leq_{\xi}$ ) — such an element exists since U is finite. We claim that

from some moment on, 
$$\pi$$
 only features subformulas of  $\delta_y$ . (8)

To prove this, note that since y is  $\leq_{\xi}$ -maximal in U, there must be a position in  $\pi$  such that y is unfolded to  $\delta_y$ , while no higher ranking variable z is unfolded at any later position in  $\pi$ .

But then a straightforward induction shows that all formulas featuring at later positions must be subformulas of  $\delta_y$ : the key case here is where  $z \leq \delta_y$  unfolds to  $\delta_z$ . Here we distinguish two cases whether  $z \in FV(\delta_y)$  or not; in the first case we use the claim below.

CLAIM 1 Let  $\varphi \leq \xi$  be such that  $z \in FV(\varphi) \cap BV(\xi)$ . Then  $\varphi \leq \delta_z$ .

PROOF OF CLAIM Let  $\ell_{\varphi}$  be the length of the shortest  $\triangleleft_0$ -path from  $\varphi$  to  $\xi$ . Then we prove by induction on  $\ell_{\varphi}$  that  $z \in FV(\varphi)$  implies  $\varphi \leq \delta_z$ . The case where  $\ell_{\varphi} = 0$  holds vacuously since here we have  $\varphi = \xi$ , and z is not free in  $\xi$ . In the inductive case we assume that  $\ell_{\varphi} > 0$ , and we consider a formula  $\psi \leq \xi$  of which  $\varphi$  is a direct subformula. We distinguish cases. If  $\psi$  is not of the form  $\psi = \lambda z.\varphi$  then we have  $z \in FV(\psi)$  so that by the inductive hypothesis we have  $\varphi \leq \psi \leq \delta_z$ . On the other hand, by cleanness of  $\xi$ , the formula  $\psi$  can only be of the form  $\psi = \lambda z.\varphi$  if  $\lambda = \eta_z$  and  $\varphi = \delta_z$ , so in this case we also have  $\varphi \leq \delta_z$ .

Returning to the main argument, if  $z \in FV(\delta_y)$  then we may infer from Claim 1 that  $\delta_y \leq \delta_z$ ; this means that  $y \leq \xi z$ , so that by the assumption of maximality we must have y = z, so that  $\delta_z$  is a subformula of  $\delta_y$  indeed. On the other hand, if  $z \notin FV(\delta_y)$  then it is not hard to see that the cleannes of  $\xi$  implies that  $\delta_z \leq \delta_y$ . QED

Given this result, there is now a natural formulation of the winning conditions for infinite matches of evaluation games.

**Definition 2.25** Let  $\xi$  be a clean  $\mu$ ML<sub>D</sub>-formula. The winning conditions of the game  $\mathcal{E}(\xi, \mathbb{S})$  are given in Table 4.

	$\exists \text{ wins } \pi \qquad \forall \text{ wins } \pi$			
$\pi$ is finite	$\forall \text{ got stuck}$	$\exists$ got stuck		
$\pi$ is infinite	$\max(Unf^{\infty}(\pi))$ is a $\nu$ -variable	$\max(Unf^{\infty}(\pi))$ is a $\mu$ -variable		

Table 4: Winning conditions of  $\mathcal{E}(\xi, \mathbb{S})$ 

We can now formulate the game-theoretic semantics of the modal  $\mu$ -calculus as follows.

**Definition 2.26** Let  $\xi$  be a clean formula of the modal  $\mu$ -calculus, and let  $\mathbb{S}$  be a transition system of the appropriate type. Then we say that  $\xi$  is (game-theoretically) *satisfied* at s, notation:  $\mathbb{S}, s \Vdash_g \xi$  if  $(\xi, s) \in \text{Win}_{\exists}(\mathcal{E}(\xi, \mathbb{S}))$ .

**Remark 2.27** As mentioned we have kept this introduction to evaluation games for fixpoint formulas rather informal, referring to Chapter 5 for a more rigorous discussion of infinite games. Nevertheless, we want to mention already here that evaluation games, on the ground of being so-called *parity games*, have two very useful properties that make them attractive to work with. To start with, every evaluation game is *determined* in the sense that every position is winning for exactly one of the two players. And second, one may show that winning strategies for either player of an evaluation game, can always be assumed to be *positional*, that is, do not depend on moves made earlier in the match, but only on the current position. Combining this, evaluation games enjoy *positional determinacy*; that is, every position ( $\varphi$ , s) is winning for exactly one of the two players, and each player  $\Pi \in \{\exists,\forall\}$  has a *positional* strategy  $f_{\Pi}$  which is winning for the game  $\mathcal{E}(\xi, \mathbb{S})@(\varphi, s)$  for every position ( $\varphi$ , s) that is winning for  $\Pi$ .

**Remark 2.28** Observe that we have defined the game-theoretic semantics for *clean* formula only. The reason for this should be obvious: at any position  $(\varphi, s)$  in the evaluation game it should be unequivocally clear what the admissible moves are, and in the case where  $\varphi$ is a (positive) literal this is only guaranteed if the ambient formula is clean. Consider for example the formula  $\xi = \Diamond p \land (\mu p.q \lor \Diamond p) \land \nu p. \Box \Diamond p$ , which has three occurrences of each of the subformulas  $\Diamond p$  and p. It should be obvious that we cannot define an adequate evaluation game for this formula based on the set  $Sf(\xi) \times S$  as positions (where S is the set of points in the Kripke model under consideration), since there is no reasonable definition of a legitimate move at a position of the form (p, s).

In the next section we define an alternative version of the evaluation game which works for the wider class of *tidy* formulas. It is certainly possible to extend this definition to arbitrary fixpoint formulas; a straightforward approach would be to involve the *construction tree* of a non-clean formula  $\xi$ , and redefine a *position* of the evaluation game  $\mathcal{E}(\xi, \mathbb{S})$  to be a pair, consisting of a node in this construction tree and a point in the Kripke structure. Alternatively, one may work with a clean *alphabetical variant* of the formula  $\xi$ ; once we have given the algebraic semantics for arbitrary formulas, it is not hard to show that in that semantics, alphabetic variants are equivalent.

#### 2.3 Examples

**Example 2.29** As a first example, consider the formulas  $\eta x.p \lor x$ , and fix a Kripke model S. Observe that any match of the evaluation game  $\mathcal{E}(\eta x.p \lor x, \mathbb{S})$  starting at position  $(\eta x.p \lor x, s)$  immediately proceeds to position  $(p \lor x, s)$ , after which  $\exists$  can make a choice. In case  $\eta$  is the least fixpoint operator,  $\eta = \mu$ , we claim that

$$\mathbb{S}, s \Vdash_q \mu x. p \lor x \text{ iff } s \in V(p).$$

For the direction from right to left, assume that  $s \in V(p)$ . Now, if  $\exists$  chooses the disjunct p at the position  $(s, p \lor x)$ , she wins the match because  $\forall$  will get stuck at (s, p). Hence  $s \in \text{Win}_{\exists}(\mathcal{E}(\mu x.p \lor x, \mathbb{S})).$ 

On the other hand, if  $s \notin V(p)$ , then  $\exists$  will lose if she chooses the disjunct p at position  $(s, p \lor x)$ . So she must choose the disjunct x which then unfolds to  $p \lor x$  so that  $\exists$  is back

at the position  $(s, p \lor x)$ . Thus if  $\exists$  does not want to get stuck, her only way to survive is to keep playing the position (s, x), thus causing the match to be infinite. But such a match is won by  $\forall$  since the only variable that gets unfolded infinitely often is a  $\mu$ -variable. Hence in this case we see that  $s \notin \operatorname{Win}_{\exists}(\mathcal{E}(\nu x. p \lor x, \mathbb{S}))$ .

If on the other hand we consider the case where  $\eta = \nu$ , then  $\exists$  can win any match:

$$\mathbb{S}, s \Vdash_a \nu x. p \lor x.$$

It is easy to see that now, the strategy of always choosing the disjunct x at a position of the form  $(s, p \lor x)$  is winning. For, it forces all games to be infinite, and since the only fixpoint variable that gets ever unfolded here is a  $\nu$ -variable, all infinite matches are won by  $\exists$ .

Concluding, we see that  $\mu x.p \lor x$  is equivalent to the formula p, and  $\nu x.p \lor x$ , to the formula  $\top$ .

**Example 2.30** Now we turn to the formulas  $\mu x . \Diamond x$  and  $\nu x . \Diamond x$ . First consider how a match for any of these formulas proceeds. The first two positions of such a match will be of the form  $(\eta x . \Diamond x, s)(\Diamond x, s)$ , at which point it is  $\exists$ 's turn to make a move. Now she either is stuck (in case the state s has no successor) or else the next two positions are  $(x, t)(\Diamond x, t)$  for some successor t of s, chosen by  $\exists$ . Continuing this analysis, we see that there are two possibilities for a match of the game  $\mathcal{E}(\eta x . \Diamond x, \mathbb{S})$ :

1. the match is an infinite sequence of positions

 $(\eta x. \Diamond x, s_0)(\Diamond x, s_0)(x, s_1)(\Diamond x, s_1)(x, s_2)\dots$ 

corresponding to an infinite path  $s_0 R s_1 R s_2 R \dots$  through S.

2. the match is a finite sequence of positions

 $(\eta x. \Diamond x, s_0)(\Diamond x, s_0)(x, s_1)(\Diamond x, s_1)\dots(\Diamond x, s_k)$ 

corresponding to a finite path  $s_0 R s_1 R \dots s_k$  through S, where  $s_k$  has no successors.

Note too that in either case it is only  $\exists$  who has turns, and that her strategy corresponds to choosing a *path* through S. From this it is easy to derive that

- $\mu x \, \diamond x$  is equivalent to the formula  $\perp$ ,
- $\mathbb{S}, s \Vdash_g \nu x . \Diamond x$  iff there is an infinite path starting at s.
  - ▶ Until operator

The examples that we have considered so far involved only a single fixpoint operator. We now look at an example containing both a least and a greatest fixpoint operator.

**Example 2.31** Let  $\xi$  be the following formula:

$$\xi = \nu x . \mu y . \underbrace{(p \land \Diamond x)}_{\alpha_p} \lor \underbrace{(\overline{p} \land \Diamond y)}_{\alpha_{\overline{p}}}$$

 $\triangleleft$ 

Then we claim that for any LTS S, and any state s in S:

 $\mathbb{S}, s \Vdash_q \xi$  iff there is some path from s on which p is true infinitely often. (9)

To see this, first suppose that there is a path  $\pi = s_0 s_1 s_2 \dots$  as described in the right hand side of (9) and suppose that  $\exists$  plays according to the following strategy:

- (a) at a position  $(\alpha_p \lor \alpha_{\overline{p}}, t)$ , choose  $(\alpha_p, t)$  if  $\mathbb{S}, t \Vdash_g p$  and choose  $(\alpha_{\overline{p}}, t)$  otherwise;
- (b) at a position  $(\diamond \varphi, t)$ , distinguish cases:
  - if the match so far has followed the path, with  $t = s_k$ , choose  $(\varphi, s_{k+1})$ ;
  - otherwise, choose an arbitrary successor (if possible).

We claim that this is a winning strategy for  $\exists$  in the evaluation game initialized at  $(\xi, s)$ . Indeed, since  $\exists$  always chooses the propositionally safe disjunct of  $\alpha_p \vee \alpha_{\overline{p}}$ , she forces  $\forall$ , when faced with a position of the form  $(\alpha_{\pm p}, t) = (\pm p \land \Diamond z, t)$  to always choose the diamond conjunct  $\Diamond z$ , or lose immediately. In this way she guarantees to always get to positions of the form  $(\Diamond z, s_i)$ , and thus she can force the match to last infinitely long, following the infinite path  $\pi$ . But why does she actually win this match? The point is that, whenever she chooses  $\alpha_p$ , three positions later, x will be unfolded, and likewise with  $\alpha_{\overline{p}}$  and y. Thus, p being true infinitely often on  $\pi$  means that the  $\nu$ -variable x gets unfolded infinitely often. And so, even though the  $\mu$ -variable y might get unfolded infinitely often as well, she wins the match since x ranks higher than y anyway.

For the other direction, assume that  $\mathbb{S}, s \Vdash_g \xi$  so that  $\exists$  has a winning strategy in the game  $\mathcal{E}(\xi, \mathbb{S})$  initialized at  $(\xi, s)$ . It should be clear that any winning strategy must follow (a) above. So whenever  $\forall$  faces a position  $(p \land \Diamond z, t), p$  will be true, and likewise with positions  $(\overline{p} \land \Diamond z, t)$ . Now consider a match in which  $\forall$  plays propositionally sound, that is, always chooses the diamond conjunct of these positions. This match must be infinite since both players will stay alive forever:  $\forall$  because he can always choose a diamond conjunct, and  $\exists$  because we assumed her strategy to be winning. But a second consequence of  $\exists$  playing a winning strategy, is that it cannot happen that y is unfolded infinitely often, while x is not. So x is unfolded infinitely often, and as before, x only gets unfolded right after the match passed a world where p is true. Thus the path chosen by  $\exists$  must contain infinitely many states where p holds.

#### 2.4 Bisimulation invariance and the bounded tree model property

Given the game-theoretic characterization of the semantics, it is rather straightforward to prove that formulas of the modal  $\mu$ -calculus are bisimulation invariant. From this it is immediate that the modal  $\mu$ -calculus has the tree model property. But in fact, we can use the game semantics to do better than this, proving that every satisfiable modal fixpoint formula is satisfied in a tree of which the branching degree is *bounded* by the size of the formula.

**Theorem 2.32 (Bisimulation Invariance)** Let  $\xi$  be a modal fixpoint formula with  $FV(\xi) \subseteq P$ , and let S and S' be two labelled transition systems with points s and s', respectively. If  $S, s \hookrightarrow_P S', s'$ , then

 $\mathbb{S}, s \Vdash_q \xi \text{ iff } \mathbb{S}', s' \Vdash_q \xi.$ 

**Proof.** Assume that  $s \cong_{\mathsf{P}} s'$  and that  $\mathbb{S}, s \Vdash_g \xi$ , with  $FV(\xi) \subseteq \mathsf{P}$ . We will show that  $\mathbb{S}', s' \Vdash_g \xi$ . By definition we may assume that  $\exists$  has a winning strategy f in the evaluation game  $\mathcal{E} := \mathcal{E}(\xi, \mathbb{S})$  initialized at  $(\xi, s)$ ; that is, given an f-guided partial  $\mathcal{E}$ -match  $\pi$  ending in a position for  $\exists$ , we let  $f(\pi)$  denote the next position as determined by f.

We need to provide her with a winning strategy in the game  $\mathcal{E}' := \mathcal{E}(\xi, \mathbb{S}')@(\xi, s')$ . She obtains her strategy f' in  $\mathcal{E}'$  from playing a *shadow match* of  $\mathcal{E}$ , using the bisimilarity relation to guide her choices.

To see how this works, let's simply start with comparing the initial position  $(\xi, s')$  of  $\mathcal{E}'$  with its counterpart  $(\xi, s)$  of  $\mathcal{E}$ . (From now on we will write  $s \Leftrightarrow s'$  instead of  $s \Leftrightarrow_{\mathsf{P}} s'$ ).

In case ξ is a literal, it is easy to see that both (ξ, s) and (ξ, s') are final positions. Also, since f is assumed to be winning, ξ must be true at s, and so it must hold at s' as well. Hence, ∃ wins the match.

If  $\xi$  is not a literal, we distinguish cases.

- First suppose that  $\xi = \xi_1 \lor \xi_2$ . If f tells  $\exists$  to choose disjunct  $\xi_i$  at  $(\xi, s)$ , then she chooses the same disjunct  $\xi_i$  at position  $(\xi, s')$ . If  $\xi = \xi_1 \land \xi_2$ , it is  $\forall$  who moves. Suppose in  $\mathcal{E}'$ he chooses  $\xi_i$ , making  $(\xi_i, s')$  the next position. We now consider in  $\mathcal{E}$  the same move of  $\forall$ , so that the next position in the shadow match is  $(\xi_i, s)$ .
- A third possibility is that  $\xi = \Diamond \psi$ . In order to make her move at  $(\xi, s')$ ,  $\exists$  first looks at  $(\xi, s)$ . Since f is a winning strategy, it indeed picks a successor t of s. Then because  $s \leq s'$ , there is a successor t' of s' such that  $t \leq t'$ . This t' is  $\exists$ 's move in  $\mathcal{E}'$ , so that  $(\psi, t)$  and  $(\psi, t')$  are the next positions in  $\mathcal{E}$  and  $\mathcal{E}'$ , respectively.
- If  $\xi = \Box \psi$ , we are dealing again with positions for  $\forall$ . Suppose in  $\mathcal{E}'$  he chooses the successor t' of s', so that the next position is  $(\psi, t')$ . (In case s' has no successors,  $\forall$  immediately loses, so that there is nothing left to prove.) Now again we turn to the shadow match; by bisimilarity of s and s' there is a successor t of s such that  $t \Leftrightarrow t'$ . So we may assume that  $\forall$  moves the game token of  $\mathcal{E}$  to position  $(\psi, t)$ .
- Finally, if  $\xi = \eta x \, \delta_x$  then the next positions in  $\mathcal{E}$  and  $\mathcal{E}'$  are, respectively,  $(\delta_x, s)$  and  $(\delta_x, s')$ .

The crucial observation is that if  $\exists$  does not win immediately, then at least she can guarantee that the next positions in  $\mathcal{E}$  and  $\mathcal{E}'$  are of the form  $(\varphi, u)$  and  $(\varphi, u')$  respectively, with  $u \leq u'$ , and such that the move in  $\mathcal{E}$  is consistent with f. We may in fact show that she can maintain this condition throughout the match, and it is not hard to see that she can construct a winning strategy based on this.

Making this proof sketch a bit more precise, we introduce some terminology (anticipating the formal treatment of games in Chapter 5). Generally we identify *matches* of a game with certain sequences of positions in that game, and we say that a match  $\pi = p_0 p_1 \dots p_n$  is guided by a strategy f for player  $\Pi \in \{\exists, \forall\}$  if for every i < n such that position  $p_i$  belongs to  $\Pi$ , the next position  $p_{i+1}$  is indeed the position dictated by the strategy f. In the context of this particular proof we say that an  $\mathcal{E}'$ -match  $\pi' = (\varphi'_0, s'_0)(\varphi'_1, s'_1) \dots (\varphi'_n, s'_n)$  is linked to an  $\mathcal{E}$ -match  $\pi = (\varphi_0, s_0)(\varphi_1, s_1) \dots (\varphi_n, s_n)$  (of the same length), if  $\varphi'_i = \varphi_i$  and  $\mathbb{S}', s'_i \mathfrak{L} \mathfrak{S}, s_i$  for all i with  $0 \leq i \leq n$ . The key claim in the proof states that, for a  $\mathcal{E}'$ -match  $\pi'$ , if  $\exists$  has established such a bisimilarity link with an  $\mathcal{E}$ -match that is f-guided, then she will either win the  $\mathcal{E}'$ -game immediately, or else she can maintain the link during one further round of the game.

CLAIM 1 Let  $\pi'$  be a finite  $\mathcal{E}'$ -match, and assume that  $\pi'$  is linked to some f-guided  $\mathcal{E}$ -match  $\pi$ . Then one of the following two cases apply.

1) both  $\mathsf{last}(\pi')$  and  $\mathsf{last}(\pi)$  are positions for  $\exists$ , and  $\exists$  can continue  $\pi'$  with a legitimate move  $(\varphi, t')$  such that  $\pi' \cdot (\varphi, t')$  is bisimilarity-linked to  $\pi \cdot (\varphi, t)$ , where  $(\varphi, t)$  is the move dicated by f in  $\pi$ .

2) both  $\mathsf{last}(\pi')$  and  $\mathsf{last}(\pi)$  are positions for  $\forall$ , and for every move  $(\varphi', t)$  for  $\forall$  in  $\pi'$  there is a legitimate move  $(\varphi, t)$  for  $\forall$  in  $\pi$  such that  $\pi' \cdot (\varphi, t')$  is bisimilarity-linked to  $\pi \cdot (\varphi, t)$ .

The *proof* of this Claim proceeds via an obvious adaptation of the case-by-case argument just given for the initial positions of  $\mathcal{E}'$  and  $\mathcal{E}$ . Omitting the details, we move on to show that based on Claim 1,  $\exists$  has a winning strategy in  $\mathcal{E}'$ .

By a straightforward inductive argument we may provide  $\exists$  with a strategy f' in  $\mathcal{E}'$ , and show how to maintain, simultaneously, for every f'-guided match  $\pi$ , an f-guided  $\mathcal{E}$ match which is linked to  $\pi'$ . For the base case of this induction, simply observe that by the assumption that  $\mathbb{S}, s \cong \mathbb{S}', s'$ , the initial positions of  $\mathcal{E}'$  and  $\mathcal{E}$  constitute linked (trivial) matches. For the inductive case we consider an f'-guided  $\mathcal{E}'$ -match  $\pi'$ , and inductively assume that there is a bisimilarity-linked f-guided  $\mathcal{E}$ -match  $\pi$ . Now distinguish cases:

- If  $last(\pi')$  is a position for  $\exists$ , we use item 1) of Claim 1 to define her move  $(\varphi, t')$ ; it follows that  $\pi' \cdot (\varphi, t')$  and  $\pi \cdot (\varphi, t)$  are bisimilarity-linked (where  $(\varphi, t)$  is the move dicated by f in  $\pi$ ).
- On the other hand, in case  $last(\pi')$  is a position for  $\forall$ , assume that he makes some move, say,  $(\psi, t')$ ; now we use item 2) of the claim to define a continuation  $\pi \cdot (\psi, t)$  of  $\pi$  that is bisimilarity-linked to  $\pi' \cdot (\psi, t')$ .

To see why the strategy f' of  $\exists$  is winning for her, consider a full (i.e., finished) f'-guided match  $\pi'$ , and distinguish cases. If  $\pi'$  is finite, this means that one of the players must be stuck, and we have to show that this player must be  $\forall$ . But we just showed that there must be an f-guided match  $\pi$  which is bisimilarity-linked to  $\pi'$ . It follows from the definiton of linked matches that the final positions of  $\pi'$  and  $\pi$  must be, respectively, of the form  $(\varphi, t')$ and  $(\varphi, t)$  for some formula  $\varphi$  and states t', t such that  $\mathbb{S}', t' \cong \mathbb{S}, t$ . From this it is not hard to derive that the same player who got stuck in  $\pi'$  also got stuck in  $\pi$ ; and since  $\pi$  is guided by  $\exists$ 's supposedly winning strategy f, this player must be  $\forall$  indeed.

If  $\pi'$  is infinite, say  $\pi' = (\varphi_i, s'_i)_{i < \omega}$ , the shadow  $\mathcal{E}$ -match maintained by  $\exists$  is infinite as well. More precisely, the inductive argument given above reveals the existence of an infinite, f-guided  $\mathcal{E}$ -match  $\pi = (\varphi_i, s_i)_{i < \omega}$  such that  $\mathbb{S}', s'_i \hookrightarrow \mathbb{S}, s_i$  for all  $i < \omega$ . The key observation, however, is that the two sequences of formulas, in the  $\mathcal{E}'$ -match  $\pi'$  and its  $\mathcal{E}$ -shadow  $\pi$ , respectively, are exactly the *same*. This means that also in the infinite case the winner of  $\pi'$ is the winner of  $\pi$ , and since  $\pi$  is f-guided, this winner must be  $\exists$ . QED As an immediate corollary, we obtain the tree model property for the modal  $\mu$ -calculus.

**Theorem 2.33 (Tree Model Property)** Let  $\xi$  be a modal fixpoint formula. If  $\xi$  is satisfiable, then it is satisfiable at the root of a tree model.

**Proof.** For simplicity, we confine ourselves to the basic modal language. Suppose that  $\xi$  is satisfiable at state s of the Kripke model S. Then by bisimulation invariance,  $\xi$  is satisfiable at the root of the *unravelling*  $\vec{\mathbb{S}}_s$  of S around s, cf. Definition 1.23. This unravelling clearly is a tree model. QED

For the next theorem, recall that the size of a formula is simply defined as the number of its subformulas.

**Theorem 2.34 (Bounded Tree Model Property)** Let  $\xi$  be a modal fixpoint formula. If  $\xi$  is satisfiable, then it is satisfiable at the root of a tree, of which the branching degree is bounded by the size  $|\xi|$  of the formula.

**Proof.** Suppose that  $\xi$  is satisfiable. By the Bisimulation Invariance Theorem it follows that  $\xi$  is satisfiable at the root r of some tree model  $\mathbb{T} = \langle T, R, V \rangle$ . So  $\exists$  has a winning strategy f in the game  $\mathcal{E}@(\xi, r)$ , where we abbreviate  $\mathcal{E} := \mathcal{E}(\xi, \mathbb{T})$ . By the Positional Determinacy of the evaluation game, we may assume that this strategy is positional — this will simplify our argument a bit. We may thus represent this strategy as a map f that, among other things, maps positions of the form  $(\diamond \varphi, s)$  to positions of the form  $(\varphi, t)$  with Rst.

We will prune the tree  $\mathbb{T}$ , keeping only the nodes that  $\exists$  needs in order to win the match. Formally, define subsets  $(T_n)_{n \in \omega}$  as follows:

$$\begin{array}{rcl} T_0 & := & \{r\}, \\ T_{n+1} & := & T_n \cup \{s \mid (\varphi, s) = f(\Diamond \varphi, t) \text{ for some } t \in T_n \text{ and } \Diamond \varphi \leqslant \xi\}, \\ T_{\omega} & := & \bigcup_{n \in \omega} T_n. \end{array}$$

Let  $\mathbb{T}_{\omega}$  be the subtree of  $\mathbb{T}$  based on  $T_{\omega}$ . (Note that  $\mathbb{T}_{\omega}$  is in general not a generated submodel of  $\mathbb{T}$ : not all successors of nodes in  $\mathbb{T}_{\omega}$  need to belong to  $\mathbb{T}_{\omega}$ .) From the construction it is obvious that the branching degree of  $\mathbb{T}_{\omega}$  is bounded by the size of  $\xi$ , because  $\xi$  has at most  $|\xi|$  diamond subformulas.

We claim that  $\mathbb{T}_{\omega}, r \Vdash_g \xi$ . To see why this is so, let  $\mathcal{E}' := \mathcal{E}(\xi, \mathbb{T}_{\omega})$  be the evaluation game played on the pruned tree. It suffices to show that the strategy f', defined as the restriction of f to positions of the game  $\mathcal{E}'$ , is winning for  $\exists$  in the game starting at  $(\xi, r)$ . Consider an arbitrary  $\mathcal{E}'$ -match  $\pi = (\xi, r)(\varphi_1, t_1) \dots$  which is consistent with f'. The key observation of the proof is that  $\pi$  is also a match of  $\mathcal{E}@(\xi, r)$ , that is consistent with f. To see this, simply observe that all moves of  $\forall$  in  $\pi$  could have been made in the game on  $\mathbb{T}$  as well, whereas by construction, all f' moves of  $\exists$  in  $\mathcal{E}'$  are f moves in  $\mathcal{E}$ .

Now by assumption, f is a winning strategy for  $\exists$  in  $\mathcal{E}$ , so she wins  $\pi$  in  $\mathcal{E}$ . But then  $\pi$  is winning as such, i.e., no matter whether we see it as a match in  $\mathcal{E}$  or in  $\mathcal{E}'$ . In other words,  $\pi$  is also winning as an  $\mathcal{E}'$ -match. And since  $\pi$  was an arbitrary  $\mathcal{E}'$ -match starting at  $(\xi, r)$ , this shows that f' is a winning strategy, as required. QED

# 2.5 The evaluation game based on the closure set

In this section we define an alternative version of the evaluation game for  $\mu$ -calculus formulas, in which the equivalence

$$\eta x \, \chi \equiv \chi [\eta x \, \chi/x]$$

is exploited more directly than in the *subformula game* that we defined in section 2.2. The idea in the *closure game* is that, at a position  $(\eta x \chi, s)$  the fixpoint formula will simply be unfolded, yielding the pair  $(\chi[\eta x \chi/x], s)$  as the (unique) next position. That is, the admissible moves in the closure game are given in Table 5.

Position	Player	Admissible moves
$(\varphi \lor \psi, s)$	Ξ	$\{(\varphi, s), (\psi, s)\}$
$(\varphi \land \psi, s)$	$\forall$	$\{(\varphi, s), (\psi, s)\}$
$ (\diamond \varphi, s) $	Ξ	$\{(\varphi,t) \mid sRt\}$
$(\Box \varphi, s)$	$\forall$	$\{(\varphi,t) \mid sRt\}$
$(p,s)$ with $p \in FV(\xi)$ and $s \in V(p)$	$\forall$	Ø
$(p,s)$ with $p \in FV(\xi)$ and $s \notin V(p)$	Ξ	Ø
$(\overline{p}, s)$ with $p \in FV(\xi)$ and $s \in V(p)$	Э	Ø
$(\overline{p}, s)$ with $p \in FV(\xi)$ and $s \notin V(p)$	$\forall$	Ø
$(\eta x. \varphi, s)$	-	$\{(\varphi[\eta x\varphi/x],s)\}$

Table 5: Positions and admissible moves in the closure evaluation game  $\mathcal{E}^{c}(\xi, \mathbb{S})$ 

In order to turn this table into a proper game, we need to introduce appropriate *winning* conditions for the two players. For this purpose we introduce some terminology and notation, and we make some observations. We start with the notion of a *trace*.

#### Traces and the closure game

**Definition 2.35** Let  $\rightarrow_C$  be the binary relation between tidy  $\mu$ -calculus formulas given by the following exhaustive list:

- 1)  $(\varphi_0 \circledast \varphi_1) \to_C \varphi_i$ , for any  $\varphi_0, \varphi_1 \in \mu \mathsf{ML}$ ,  $\circledast \in \{\land, \lor\}$  and  $i \in \{0, 1\}$ ;
- 2)  $\heartsuit \varphi \to_C \varphi$ , for any  $\varphi \in \mu \mathsf{ML}$  and  $\heartsuit \in \{\diamondsuit, \Box\}$ );
- 3)  $\eta x. \varphi \to_C \varphi[\eta x. \varphi/x]$ , for any  $\eta x. \varphi \in \mu ML$ , with  $\eta \in \{\mu, \nu\}$ .

We call a  $\rightarrow_C$ -path  $\psi_0 \rightarrow_C \psi_1 \rightarrow_C \cdots \rightarrow_C \psi_n$  a *(finite) trace*; similarly, an *infinite trace* is a sequence  $(\psi_i)_{i < \omega}$  such that  $\psi_i \rightarrow_C \psi_{i+1}$  for all  $i < \omega$ .

Intuitively a trace is a sequence that corresponds to the formula part of a possible match of the closure game. The *closure* of a formula consists of the formulas that can be encountered in such a match.

**Definition 2.36** We define the relation  $\twoheadrightarrow_C$  as the reflexive and transitive closure of  $\rightarrow_C$ , and define the *closure* of a tidy formula  $\xi$  as the set

$$Cl(\xi) := \{ \varphi \mid \xi \twoheadrightarrow_C \varphi \}.$$

Given a set of formulas  $\Psi$ , we put  $Cl(\Psi) := \bigcup_{\xi \in \Psi} Cl(\xi)$ , and we call  $\Psi$  closed if  $\Psi = Cl(\Psi)$ . Formulas in the set  $Cl(\xi)$  are said to be *derived* from  $\xi$ . The closure graph of  $\xi$  is the directed graph  $\mathbb{C}_{\xi} := (Cl(\xi), \to_C)$ .

In words,  $Cl(\xi)$  is the smallest set which contains  $\xi$  and is closed under direct boolean and modal subformulas, and under unfoldings of fixpoint formulas. In terms of traces: a formula  $\chi$  belongs to the closure of a formula  $\xi$  iff there is a trace from  $\xi$  to  $\chi$ . Furthermore, a trace starting at  $\xi$  is nothing but a path in the closure graph starting at  $\xi$ .

**Remark 2.37** The final example of Remark 2.17 shows that the closure of a non-tidy formula may not even be defined — unless we work with alphabetical variants. We will come back to this point later.  $\triangleleft$ 

The following example will be instructive for understanding the concept of closure, and its relation with subformulas.

**Example 2.38** Consider the following formulas:

$\xi_1$	:=	$\mu x_1 \nu x_2 \mu x_3. (((x_1 \lor x_2) \lor x_3) \land \Box ((x_1 \lor x_2) \lor x_3))$
$\xi_2$	:=	$\nu x_2 \mu x_3. \big( ((\xi_1 \lor x_2) \lor x_3) \land \Box ((\xi_1 \lor x_2) \lor x_3) \big)$
$\xi_3$	:=	$\mu x_3. \big( ((\xi_1 \lor \xi_2) \lor x_3) \land \Box ((\xi_1 \lor \xi_2) \lor x_3) \big)$
$\xi_4$	:=	$\left(\left((\xi_1 \lor \xi_2) \lor \xi_3 ight) \land \Box\left((\xi_1 \lor \xi_2) \lor \xi_3 ight) ight)$
$\alpha$	:=	$(\xi_1 \lor \xi_2) \lor \xi_3$
$\beta$	:=	$\xi_1 \lor \xi_2,$

and let  $\Phi$  be the set  $\Phi := \{\xi_1, \xi_2, \xi_3, \xi_4, \Box \alpha, \alpha, \beta\}.$ 

For i = 1, 2, 3, the formula  $\xi_{i+1}$  is the unfolding of the formula  $\xi_i$ . Thus we find  $Cl(\xi_1) = \Phi$ ; in fact, we have  $Cl(\varphi) = \Phi$  for every formula  $\varphi \in \Phi$ . In Figure 2 we depict the *closure graph* of  $\xi_1$ .

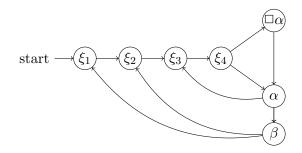

Figure 2: A closure graph

Observe that the formulas  $\xi_1, \xi_2, \xi_3$  and  $\xi_4$  are equivalent to one another, and hence also to  $\alpha$ . Note too that the formula  $\xi_1$  is the only clean formula in  $\Phi$ , and that it is a subformula of *every* formula in  $Cl(\xi_1)$ .

The closure of  $\xi$  consists of the formulas that one may encounter in a match of the closure game  $\mathcal{E}^{c}(\xi, \mathbb{S})$ , and, as a consequence of this, we will take  $Cl(\xi) \times S$  as the set of positions in this game. As we will see now, the key observation for defining the winning conditions of this game is that every infinite trace can be identified as either a  $\mu$ -trace or a  $\nu$ -trace. This is in some sense the analogon of Proposition 2.24.

**Proposition 2.39** 1) Let  $\tau$  be a finite trace. Then there is a unique formula on  $\tau$  which is a subformula of every formula on  $\tau$ .

2) Let  $\tau$  be a infinite trace. Then there is a unique formula which appears infinitely often on  $\tau$ , and is a subformula of cofinitely many formulas on  $\tau$ . This formula is always a fixpoint formula.

**Proof.** The reader is asked to supply a proof of this Proposition in Exercise 2.9. QED

**Definition 2.40** Let  $\tau$  be an infinite trace. The formula  $\eta x \varphi$  which appears infinitely often on  $\tau$  and is a subformula of cofinitely formulas on  $\tau$  is called the *most significant formula* of  $\tau$ , notation:  $msf(\tau)$ . Depending on the nature of  $\eta$  we call  $\tau$  either a  $\mu$ -trace or a  $\nu$ -trace.

For future reference we define some relations. We write  $\rho \twoheadrightarrow_C^{\psi} \sigma$  if there is a trace  $\rho = \chi_0 \rightarrow_C \chi_1 \rightarrow_C \cdots \rightarrow_C \chi_n = \sigma$  such that  $\psi \leq \chi_i$ , for every  $i \in [0, n]$ . We write  $\rho \twoheadrightarrow_C^{\eta} \sigma$  (for  $\eta \in \{\mu, \nu\}$ ) if we have  $\rho \twoheadrightarrow_C^{\psi} \sigma$  for some  $\eta$ -formula  $\psi$ , and  $\rho \twoheadrightarrow_C^o \sigma$  if  $\rho \twoheadrightarrow_C^{\psi} \sigma$  for some formula  $\psi$  which is not a fixpoint formula.

The classification of infinite traces as either  $\mu$ - or  $\nu$ -traces enables us to complete the definition of the closure game.

**Definition 2.41** Let  $\mathbb{S} = (S, R, V)$  be a Kripke model and let  $\xi$  be a tidy formula in  $\mu$ ML. We define the *evaluation game*  $\mathcal{E}^{c}(\xi, \mathbb{S})$  as the game  $(G, E, \Omega)$  of which the board consists of the set  $Cl(\xi) \times S$ , and the game graph (i.e., the partitioning of  $Cl(\xi) \times S$  into positions for the two players, together with the set E(z) of admissible moves at each position), is given in Table 5.

The winner of an infinite match  $\pi = (\xi_n, s_n)_{n < \omega}$  is  $\exists$  if its left projection  $\pi_L := (\xi_n)_{n < \omega}$  is a  $\nu$ -trace, and  $\forall$  if it is a  $\mu$ -trace.

#### The closure operation

The closure operation is one of the most fundamental tools in the theory of the modal  $\mu$ calculus, and in this subsection we discuss some of its properties, the most important being Proposition 2.45 stating that the closure of a finite set is always finite.

We first gather some basic observations. To start with, while Example 2.38 clearly shows that, while the unfolding of a clean formula will generally not be clean, tidyness is preserved.

**Proposition 2.42** Let  $\xi \in \mu$ ML be a tidy formula, and let  $\varphi$  be derived from  $\xi$ . Then 1)  $BV(\varphi) \subseteq BV(\xi)$  and  $FV(\varphi) \subseteq FV(\xi)$ ;

<sup>2)</sup>  $\varphi$  is tidy;

3) if  $\psi$  is free for x in  $\xi$  and  $\xi[\psi/x]$  is tidy then  $\psi$  is also free for x in  $\varphi$ , and  $\varphi[\psi/x]$  is tidy.

**Proof.** The proofs of the first two items proceed by a straightforward induction on the trace  $\xi \twoheadrightarrow_C \varphi$ . For instance, for the preservation of tidyness it suffices to prove that  $\chi$  is tidy if  $\heartsuit \chi$  is so (where  $\heartsuit \in \{\diamondsuit, \square\}$ ), that  $\chi_0$  and  $\chi_1$  are tidy if  $\chi_0 \circledast \chi_1$  is so (where  $\circledast \in \{\land, \lor\}$ ), and that the unfolding of a tidy formula is tidy again. The proofs of the first two claims are easy, and the third claim was stated in Proposition 2.18.

For part 3) we also reason by induction on the length of the trace  $\tau : \xi \to_C \varphi$ . We focus on the key inductive case where  $\tau : \xi \to_C \xi' \to_C \varphi$ , and  $\xi'$  is a fixpoint formula, say,  $\xi' = \eta y \chi$ ; in this case we find  $\varphi = \chi[\xi'/y]$ . The inductive hypothesis states that  $\psi$  is free for x in  $\xi'$  and that  $\xi'[\psi/x]$  is tidy. By definition of freeness we can make the following case distinction. If x is not free in  $\xi'$  then it is not free in  $\chi[\xi'/x]$  either, which immediate implies that  $\psi$  is free for x in  $\chi[\xi'/x]$ , and that  $\varphi[\psi/x] = \chi[\xi'/x][\psi/x] = \chi[\xi'/x]$ , so that  $\varphi[\psi/x]$  is tidy by part 2).

In the remainder we focus on the case where  $y \notin FV(\psi)$  and  $\psi$  is free for x in  $\chi$ . Clearly it suffices to show that

$$\psi$$
 is free for  $x$  in  $\rho[\xi'/y]$ , for every  $\rho \leq \chi$ . (10)

We prove (10) by induction on  $\rho$  and only consider the key case, where  $\rho$  is a fixpoint formula, say,  $\rho = \lambda z \rho'$ . Then by the inner induction hypothesis we have that  $\psi$  is free for x in  $\rho'$ . Now assume for contradiction that  $\psi$  is *not* free for x in  $\rho'$ ; this can only be the case if z itself is free in  $\psi$ . We leave it for the reader to verify that this implies that z has both free and bound occurrences in  $\xi'[\psi/x]$ , contradicting the tidyness of  $\xi'$ . QED

Second, the following proposition states that Cl is indeed a closure operation. We leave the proof of this proposition as an exercise for the reader.

**Proposition 2.43** Cl is a closure operation on the collection of tidy formulas:

1)  $\Phi \subseteq Cl(\Phi);$ 2) Cl is monotone:  $\Phi \subseteq \Psi$  implies  $Cl(\Phi) \subseteq Cl(\Psi);$ 3)  $Cl(Cl(\Phi)) \subseteq Cl(\Phi).$ 

The proposition below will prove to be very useful. It details how the closure map interacts with various connectives and formula constructors of the  $\mu$ -calculus.

**Proposition 2.44** Let  $\xi$  be a tidy formula. Then the following hold.

- 1) Let  $\ell \leq \xi$  be a literal occurring in  $\xi$ , and assume that  $\ell \notin BV(\xi)$ . Then  $\ell \in Cl(\xi)$ .
- 2) If  $\xi = \heartsuit \chi$ , then  $\chi$  is tidy and  $Cl(\xi) = \{\heartsuit \chi\} \cup Cl(\chi)$ , where  $\heartsuit \in \{\diamondsuit, \square\}$ .
- 3) If  $\xi = \chi_0 \circledast \chi_1$  then both  $\chi_i$  are tidy and  $Cl(\xi) = \{\chi_0 \circledast \chi_1\} \cup Cl(\chi_0) \cup Cl(\chi_1)$ , where  $\circledast \in \{\land, \lor\}$ .
- 4) If  $\xi = \chi[\psi/x]$ ,  $\chi$  is tidy,  $x \in FV(\chi)$  and  $\psi$  is free for x in  $\chi$ , then  $\psi$  is tidy and

$$Cl(\xi) = \{\varphi[\psi/x] \mid \varphi \in Cl(\chi)\} \cup Cl(\psi)$$

5) Let  $\xi = \eta x \cdot \chi$ , where  $\eta \in {\mu, \nu}$ ; assume that  $x \in FV(\chi)$ , and let  $x^*$  be some fresh variable. Then  $\chi[x^*/x]$  is tidy and

$$Cl(\xi) = \{\varphi[\eta x.\chi/x^*] \mid \varphi \in Cl(\chi[x^*/x])\}.$$
(11)

Before we turn to the proof of Proposition 2.44, we briefly comment on the formulation of part 5). Note that if  $\xi$  is of the form  $\xi = \eta x \chi$ , then  $\chi$  is not necessarily tidy, so that  $Cl(\chi)$  may not be defined. For this reason we use a fresh propositional variable  $x^*$ . However, in case  $\chi$  is tidy, (11) simplifies to

$$Cl(\xi) = \{\varphi[\eta x.\chi/x] \mid \varphi \in Cl(\chi)\}.$$
(12)

**Proof.** We prove the first and fourth claim of the proposition, leaving the other parts to the reader. The second and third claim are easy to prove, and part 5) is a fairly direct consequence of part 4).

For the first item, define the *height* of  $\ell$  in  $\xi$  as the length of the shortest chain of the form  $\varphi_0 \triangleleft_0 \varphi_1 \triangleleft_0 \cdots \triangleleft_0 \varphi_n$  such that  $\varphi_0 = \ell$ ,  $\varphi_n = \xi$ , and, in case  $\ell$  is a propositional variable p, no formula  $\varphi_i$  is of the form  $\eta p \psi$ . It is then straightforward to prove that  $\ell \in Cl(\xi)$  by induction on the height of  $\ell$  in  $\xi$ . We leave the details for the reader.

For the proof of 4), assume that  $x \in FV(\chi)$  and that  $\psi$  is free for x in  $\chi$ . By Proposition 2.42(3), the formula  $\psi$  is free for x in every  $\varphi \in Cl(\chi)$ . To prove the inclusion  $\subseteq$  it suffices to show that the set  $\{\varphi[\psi/x] \mid \varphi \in Cl(\chi)\} \cup Cl(\psi)\}$  has the required closure properties. This is easily verified, and so we omit the details.

For the opposite inclusion, we first show that

$$\varphi[\psi/x] \in Cl(\chi[\psi/x]), \text{ for all } \varphi \in Cl(\chi),$$
(13)

and we prove this by induction on the trace from  $\xi$  to  $\varphi$ . It is immediate by the definitions that  $\chi[\psi/x] \in Cl(\chi[\psi/x])$ , which takes care of the base case of this induction.

In the inductive step we distinguish three cases. First, assume that  $\varphi \in Cl(\chi)$  because the formula  $\heartsuit \varphi \in Cl(\chi)$ , with  $\heartsuit \in \{\diamondsuit, \square\}$ . Then by the inductive hypothesis we find  $\heartsuit \varphi[\psi/x] = (\heartsuit \varphi)[\psi/x] \in Cl(\chi[\psi/x])$ ; but then we may immediately conclude that  $\varphi[\psi/x] \in Cl(\chi[\psi/x])$  as well. The second case, where we assume that  $\varphi \in Cl(\chi)$  because there is some formula  $\varphi \circledast \varphi'$  or  $\varphi' \circledast \varphi$  in  $Cl(\chi)$  (with  $\circledast \in \{\land, \lor\}$ ), is dealt with in a similar way.

In the third case, we assume that  $\varphi \in Cl(\chi)$  is of the form  $\varphi = \rho[\lambda y.\rho/y]$ , with  $\lambda \in \{\mu, \nu\}$ and  $\lambda y.\rho \in Cl(\chi)$ . Then inductively we may assume that  $(\lambda y.\rho)[\psi/x] \in Cl(\chi[\psi/x])$ . Now we make a case distinction: if x = y we find that  $(\lambda y.\rho)[\psi/x] = \lambda y.\rho$ , while at the same time we have  $\varphi[\psi/x] = \rho[\lambda y.\rho/y][\psi/x] = \rho[\lambda y.\rho/y]$ , so that it follows by the closure properties that  $\varphi[\psi/x] \in Cl(\chi[\psi/x])$  indeed. If, on the other hand, x and y are distinct variables, then we find  $(\lambda y.\rho)[\psi/x] = \lambda y.\rho[\psi/x]$ , and so it follows by the closure properties that the formula  $(\rho[\psi/x])[\lambda y.\rho[\psi/x]/y]$  belongs to  $Cl(\chi[\psi/x])$ . But since  $\psi$  is free for x in  $\chi$ , the variable yis not free in  $\psi$ , and so a straightforward calculation shows that  $(\rho[\psi/x])[\lambda y.\rho[\psi/x]/y] = \rho[\lambda y.\rho/y][\psi/x] = \varphi[\psi/x]$ , and so we find that  $\varphi[\psi/x] \in Cl(\chi[\psi/x])$  in this case as well. This proves (13).

To see why this implies part 4) of the proposition, it remains to show that  $Cl(\psi) \subseteq Cl(\xi)$ . But from  $x \in FV(\chi)$  we infer  $x \in Cl(\chi)$  by part 1), and from this we obtain that  $\psi = x[\psi/x] \in Cl(\xi)$ . This suffices by Proposition 2.43. QED As an almost immediate corollary of Proposition 2.44 we find that the closure set of a  $\mu$ -calculus formula is always *finite*.

**Proposition 2.45** Let  $\xi \in \mu ML$  be some formula. Then the set  $Cl(\xi)$  is finite.

**Proof.** We prove the proposition by induction on the *length* of a formula, as defined in Definition 2.5. More precisely, we claim that

$$|Cl(\xi)| \le |\xi|^{\ell} \tag{14}$$

for every tidy formula  $\xi \in \mu ML$ .

In case  $\xi$  is a formula of length 1 it must be atomic, so (14) is obvious. For the inductive case we consider a formula  $\xi$  with  $|\xi|^{\ell} > 1$ ; such a formula cannot be atomic, and so it must be a boolean, modal or fixpoint formula. We now make a case distinction, only considering the cases where  $\xi$  is a conjunction or a  $\mu$ -formula.

First let  $\xi$  be of the form  $\xi = \xi_0 \wedge \xi_1$ . By Proposition 2.44(3) we obtain  $|Cl(\xi)| \leq |Cl(\xi_0)| + |Cl(\xi_1)|$ , and the induction hypothesis yields  $|Cl(\xi_i)| \leq |\xi_i|^{\ell}$ . Thus we find  $|Cl(\xi)| \leq |\xi_0|^{\ell} + |\xi_1|^{\ell} < |\xi|^{\ell}$ .

If  $\xi$  is of the form  $\xi = \mu x \chi$  we further distinguish cases. If x is not free in  $\chi$  we have  $\chi[\xi/x] = \chi$  and so  $Cl(\xi) = \{\xi\} \cup Cl(\chi)$ . Thus, using the induction hypothesis on  $\chi$ , we obtain  $|Cl(\xi)| \leq 1 + |Cl(\chi)| \leq 1 + |\chi|^{\ell} = |\xi|^{\ell}$ , as required. On the other hand, if x does occur freely in  $\chi$ , by Proposition 2.44(5) we find  $|Cl(\xi)| \leq |Cl(\chi[x^*/x])|$ . But since  $\chi[x^*/x]$  has the same length as  $\chi$  we may use the induction hypothesis for it; this gives  $|Cl(\chi[x^*/x])| \leq |\chi[x^*/x]|^{\ell} = |\chi|^{\ell}$ . Combining these observations we find that  $|Cl(\xi)| \leq |\chi|^{\ell} = |\xi|^{\ell} - 1$  which obviously suffices to prove (14). QED

#### 2.6 Measuring formulas

If we are interested in the complexity of algorithms for, e.g., model checking of a formula on a model, or satisfiability checking of a formula, we will see that two measures of a formulas feature prominently: its size and its alternation depth. Both notions are in fact quite subtle in that they admit several non-equivalent definitions.

# Size

When it comes to *size*, there are at least three definitions that look reasonable, at first sight: in principle one could define the size of a formula as its *length*, its *subformula-size*, or its *closure-size*. Each definition corresponds to a certain way of *representing* a formula as a graph-based structure: the length of a formula corresponds to the number of nodes in its syntax tree, its subformula-size to the number of nodes in its subformula graph, and its closure-size to the size of its closure graph. In later chapters we will see that the main complexity results on  $\mu$ -calculus formulas are actually proved using algorithms that operate on such graph-based representations. As a key example, the algorithm for *model checking* a  $\mu$ -calculus formula in a pointed model is based on computing the winner of the associated evaluation game, and the two versions of the evaluation game that we have seen in this chapter crucially involve, respectively, the subformula graph and the closure graph of a formula. In other words, much more than just picking a number and referring to it as 'the size' of a formula, the more fundamental discussion concerns the various graph-based representations of a formula.

**Definition 2.46** The *closure-size*  $|\xi|$  of a tidy formula  $\xi$  is given by

$$|\xi|^c := |Cl(\xi)|,$$

i.e., it is defined as the number of formulas that are derived from  $\xi$ . The *subformula-size* of a clean formula  $\xi$  is defined as follows:

$$|\xi|^s := |Sf(\xi)|,$$

i.e.,  $|\xi|^s$  is given as the number of subformulas of  $\xi$ .

Note that while the notion of *length* applies to all formulas, this is different for the other two measures. In Remark 2.28 we saw that it only makes sense to define the subformula-based evaluation game for clean formulas. For this reason we restrict the definition of subformulasize to clean formulas, and for similar reasons we only define the closure-size for tidy formulas. These definitions could be extended to arbitrary formulas by considering alphabetical variants, but we shall have no need to do so.

In the remark below we discuss the advantages and disadvantages of the three different ways to represent  $\mu$ -calculus formulas.

**Remark 2.47** The tree representation and the associated concept of length are very useful when giving inductive definitions and proofs but not so convenient for algorithmic purposes because of the unnecessarily unwieldy size of trees. For instance, it is well-known that the

subformula-size of a formula can be exponentially smaller than its length, as is witnessed by the sequence of formulas  $(\xi_n)_{n\in\omega}$  given by  $\xi_0 := p, \xi_{n+1} := (\xi_n \wedge \xi_n)$ . It is easy to see that the length of these formulas grows exponentially, whereas their subformula size grows linearly. For this reason in the sequel we leave the tree representations out of the picture and focus on a comparison between the subformula graph and the closure graph.

At first sight it seems more intuitive to work with subformulas because they are part of the formula itself, therefor always shorter, and they seamlessly fit with the natural inductive definition of formulas. Contrary to this, when defining the closure set of a formula, one easily get entangled in the complexities of performing substitutions which produce unreadably long formulas. In addition, proofs using the closure set can be more involved because we cannot always use straightforward inductive arguments.

Despite of this we argue that often the more natural representation of a  $\mu$ -calculus formula is its closure graph, for the following reasons.

To start with, we already saw that working with subformulas makes sense for *clean* formulas only, while the closure set is well defined for all tidy formulas, which form a substantially larger class of formulas. Related to this but more importantly, recall that the equivalence of a fixpoint formula to its *unfolding* lies at the core of the semantics of the modal  $\mu$ -calculus. The fact that the closure set of a formula is closed under taking unfoldings by design makes derived formulas more natural to work with than subformulas. For instance, this feature allows for a very smooth development of tableaux and derivation systems for  $\mu$ ML in Chapter 7, where the natural rule for fixpoint formulas simply means to unfold them.

Second, in Chapter 6 we will see that, perhaps counterintuitively, the closure graph of a formula can be *exponentially smaller* than its subformula graph. More precisely, Proposition 6.55 provides a sequence of formulas  $(\xi_n)_{n\in\omega}$  of which the subformula-size grows exponentially, while the closure-size only grows linearly. Combining this with the above discussion one could say that

 $Sf(\xi)$  is a large set of short expressions,  $Cl(\xi)$  is a small set of long expressions.

When it comes to complexity issues, the point is that key algorithms such as model checking work as fast on the subformula graph as on the closure graph. This means that we obtain *sharper* results if we measure the size of a formula as its closure-size.  $\triangleleft$ 

**Definition 2.48** The *size* of a tidy formula  $\xi$  is given as its closure-size:  $|\xi| := |\xi|^c$ .

- ▶ define size for arbitrary formulas?
- ▶ discuss size wrt alphabetical variance?

#### Alternation depth

After size, the most important complexity measure of modal  $\mu$ -calculus formulas concerns the degree of nesting of least- and greatest fixpoint operators in the syntax tree (or dag) of the formula. Intuitively, the *alternation depth* of a formula  $\xi$  will be defined as the length of a maximal chain of nested, alternating fixpoint operators. As in the case of size, there is more than one reasonable way to make this intuition precise

Example 2.49 As a first example, consider the formula

$$\xi_1 = \mu x.(\nu y.p \land \Box y) \lor \diamondsuit x,$$

expressing the reachability of some state from which only *p*-states will be reachable. Clearly this formula features a  $\nu$ -operator in the scope of a  $\mu$ -operator, and in the most straightforward approach one might indeed take this as nesting, and define the (simple) alternation depth of the formula  $\xi_1$  as 2. However, a closer inspection of the formula  $\xi_1$  reveals that, since the variable *x* does not occur in the subformula  $\nu y.p \wedge \Box y$ , the latter subformula does not really depend on *x*. This is different in the following example:

$$\xi_2 = \nu x.\mu y.(p \land \Diamond x) \lor \Diamond y,$$

stating the existence of a path on which p is true infinitely often. Here the variable x does occur in the subformula  $\mu y.(p \land \Diamond x) \lor \Diamond y$ ; that is,  $\xi_2$  contains a 'real'  $\nu/\mu$ -chain of fixpoint operators. In the definition of alternation depth ad that we shall adopt, we will see that  $\mathsf{ad}(\xi_2) = 2$  but  $\mathsf{ad}(\xi_1) = 1$ .

The formal definition of alternation depth involves inductively defined formula collections  $\Theta_n^{\eta}$ , where  $\eta \in \{\mu, \nu\}$  and n is a natural number. Intuitively, the class  $\Theta_n^{\eta}$  consists of those  $\mu$ -calculus formulas where n bounds the length of any alternating nesting of fixpoint operators of which the most significant formula is an  $\eta$ -formula. Recall our notation  $\overline{\mu} = \nu$ ,  $\overline{\nu} = \mu$ .

**Definition 2.50** By natural induction we define classes  $\Theta_n^{\mu}, \Theta_n^{\nu}$  of  $\mu$ -calculus formulas. With  $\eta, \lambda \in \{\mu, \nu\}$  arbitrary, we set:

- 1. all atomic formulas belong to  $\Theta_0^{\eta}$ ;
- 2. if  $\varphi_0, \varphi_1 \in \Theta_n^{\eta}$ , then  $\varphi_0 \vee \varphi_1, \varphi_0 \wedge \varphi_1, \Diamond \varphi_0, \Box \varphi_0 \in \Theta_n^{\eta}$ ;
- 3. if  $\varphi \in \Theta_n^{\eta}$  then  $\overline{\eta} x. \varphi \in \Theta_n^{\eta}$ ;
- 4. if  $\varphi(x), \psi \in \Theta_n^{\eta}$ , then  $\varphi[\psi/x] \in \Theta_n^{\eta}$ , provided that  $\psi$  is free for x in  $\varphi$ ;
- 5. all formulas in  $\Theta_n^{\lambda}$  belong to  $\Theta_{n+1}^{\eta}$ .

The alternation depth  $\mathsf{ad}(\xi)$  of a formula  $\xi$  is defined as the least n such that  $\xi \in \Theta_n^{\mu} \cap \Theta_n^{\nu}$ . A formula is alternation free if it has alternation depth at most 1.

Roughly, we obtain  $\Theta_0^{\mu}$  by closing the set of basic modal formulas under the boolean and modal operators, and the *greatest* fixpoint operator; and similarly for  $\Theta_0^{\nu}$ . Inductively, we obtain  $\Theta_{n+1}^{\eta}$  by closing the set  $\Theta_n^{\overline{\eta}}$  under the boolean and modal operations, substitution, and the  $\overline{\eta}$ -operator.

**Remark 2.51** In the literature one usually sees the alternation hierarchy defined in terms of classes  $\Sigma_n$  and  $\Pi_n$ , with the notation taken from the arithmetical hierarchy. The connection with our notation is as follows:

$$\begin{split} \Sigma_0 &:= \Theta_0^{\mu} \cap \Theta_0^{\nu} \qquad \Sigma_{n+1} &:= \Theta_n^{\nu} \\ \Pi_0 &:= \Theta_0^{\mu} \cap \Theta_0^{\nu} \qquad \Pi_{n+1} &:= \Theta_n^{\mu}. \end{split}$$

Our notation, which uses  $\mu$  and  $\nu$  as superscripts, allows to exploit the symmetry between  $\mu$  and  $\nu$  more directly, and may thus make the definition of alternation depth a bit easier.

**Example 2.52** Observe that the basic modal (i.e., fixpoint-free) formulas are exactly the ones with alternation depth zero. Formulas that use  $\mu$ -operators or  $\nu$ -operators, but not both, have alternation depth 1. For example, observe that  $\mu x.p \vee x$  belongs to  $\Theta_0^{\nu}$  but not to  $\Theta_0^{\mu}$ : none of the clauses in Definition 2.50 is applicable. On the other hand, using clause (5) it is easy to see that  $\mu x.p \vee x \in \Theta_1^{\nu} \cap \Theta_1^{\mu}$ , from which it is immediate that  $\operatorname{ad}(\mu x.p \vee x) = 1$ .

Returning to Example 2.49, consider the formula  $\xi_1 = \mu x.(\nu y.p \land \Box y) \lor \diamondsuit x$ . Taking a fresh variable q, we find  $\mu x.q \lor \diamondsuit x \in \Theta_0^{\nu} \subseteq \Theta_1^{\nu}$  and  $\nu y.p \land \Box y \in \Theta_0^{\mu} \subseteq \Theta_1^{\nu}$ , so that by the substitution rule we have  $\xi_1 = (\mu x.q \lor \diamondsuit x)[\nu y.p \land \Box y/q] \in \Theta_1^{\nu}$ . Similarly we may show that  $\xi_1 \in \Theta_1^{\mu}$ , so that  $\xi_1$  has alternation depth 1.

The formula  $\xi_2 = \nu x . \mu y . (p \land \Diamond x) \lor \Diamond y$  is of higher complexity. It is clear that the formula  $\mu y . (p \land \Diamond x) \lor \Diamond y$  belongs to  $\Theta_0^{\nu}$  but not to  $\Theta_0^{\mu}$ . From this it follows that  $\xi_2$  belongs to  $\Theta_1^{\mu}$  but there is no way to place it in  $\Theta_1^{\nu}$ . Hence we find that  $\mathsf{ad}(\xi_2) = 2$ .

As a final example, consider the formula

$$\xi_3 = \mu x.\nu y.(\Box y \land \mu z.(\diamondsuit x \lor z)).$$

This formula looks like a  $\mu/\nu/\mu$ -formula, in the sense that it contains a nested fixpoint chain  $\mu x/\nu y/\mu z$ . However, the variable y does not occur in the subformula  $\mu z.(\Diamond x \lor z)$ , and so the variable z is not dependent on y. Consequently we may in fact consider  $\xi_3$  as a  $\mu/\nu$ -formula. Formally, we observe that  $\mu z.\Diamond x \lor z \in \Theta_0^\nu \subseteq \Theta_1^\nu$  and  $\nu z.\Box y \land p \in \Theta_0^\mu \subseteq \Theta_1^\nu$ ; from this it follows by the substitution rule that the formula  $\nu y.(\Box y \land \mu z.(\Diamond x \lor z))$  belongs to the set  $\Theta_1^\nu$  as well; from this it easily follows that  $\xi_3 \in \Theta_1^\nu$ . It is not hard to show that  $\xi_3 \notin \Theta_1^\mu$ , so that we find  $\mathsf{ad}(\xi_3) = 2$ .

In Chapter 6 we will make precise the link between the formally defined alternation depth of a formula and the more intuitive notion of alternating chains of bound variables (in the case of clean formulas) and of fixpoint formulas (in the case of tidy formulas).

**Remark 2.53** A natural question is whether the alternation *hierarchy* is *strict*; that is, whether there are formulas of arbitrary alternation depth. The (affirmative) answer to this question will be given in Chapter ??.  $\triangleleft$ 

We finish our discussion of alternation depth here by mentioning that each class  $\Theta_n^{\eta}$  is closed under taking subformulas and derived formulas.

**Proposition 2.54** Let  $\xi$  and  $\chi$  be  $\mu$ -calculus formulas. Then the following hold:

$$if \xi \in \Theta_n^\eta \text{ and } \varphi \leqslant \xi \quad then \ \varphi \in \Theta_n^\eta \tag{15}$$

$$if \xi \in \Theta_n^\eta \text{ and } \xi \twoheadrightarrow_C \varphi \quad then \ \varphi \in \Theta_n^\eta \tag{16}$$

As a corollary, we have  $\operatorname{ad}(\chi) \leq \operatorname{ad}(\xi)$  if  $\xi$  is clean and  $\chi \in Sf(\xi)$ , or  $\xi$  is tidy and  $\chi \in Cl(\xi)$ .

**Proof.** The statement in (15) can be proved by a straightforward induction on the derivation of  $\xi \in \Theta_n^{\eta}$  — we leave the details for the reader.

To prove (16), it suffices to show that the class  $\Theta_n^{\eta}$  is closed under unfoldings, since by (15) we already know it to be closed under subformulas. So assume that  $\lambda x. \chi \in \Theta_n^{\eta}$  for some n and  $\lambda \in \{\mu, \nu\}$ . Because  $\chi \leq \eta x. \chi$  it follows from (15) that  $\chi \in \Theta_n^{\lambda}$ . But then we may apply clause (4) from Definition 2.50 and conclude that  $\chi[\eta.\chi/x] \in \Theta_n^{\lambda}$ . QED

## 2.7 Substitutions and free subformulas

In this section we discuss some further syntactic issues related to the modal  $\mu$ -calculus. None of these is of high intrinsic importance, but all concepts and results that we introduce or prove here will play a role in the development of the general theory.

# Substitution lemmas

We start with proving some lemmas on substitution. The following proposition is a well known observation in areas where syntax is used that features variable binding. Note however that our version below is a bit subtler than usual since we do not allow the renaming of bound variables.

**Proposition 2.55** Let  $\varphi, \chi$  and  $\rho$  be  $\mu$ -calculus formulas, and let x and y be distinct variables such that x is free in  $\varphi$  but not in  $\rho$ . Furthermore, assume that  $\chi$  is free for x in  $\varphi$  and that  $\rho$  is free for y in  $\varphi[\chi/x]$ . Then  $\rho$  is free for y in both  $\varphi$  and  $\chi, \chi[\rho/y]$  is free for x in  $\varphi[\rho/y]$ , and we have

$$\varphi[\chi/x][\rho/y] = \varphi[\rho/y][(\chi[\rho/y])/x].$$
(17)

**Proof.** The proposition can be proved by a straightforward but rather tedious induction on the complexity of  $\varphi$ . We omit details. QED

A major theme in this book is to study representations of formulas as *structures*, that is, sets with additional relations and operations. It will be of interest to study the properties of substitutions seen as maps between such structures. The next proposition states that substitutions have the characteristic property of bounded morphisms, with respect to the trace relation.

**Proposition 2.56 (Back- and forth property of substitution)** Let  $\xi$  and  $\chi$  be tidy  $\mu$ calculus formulas such that  $\chi[\xi/x]$  is tidy. Then the substitution operation  $\xi/x : Cl(\chi) \to \mu ML$ satisfies the following back- and forth condition, for every  $\varphi \in Cl(\chi) \setminus \{x\}$ :

$$\{\chi \mid \varphi[\xi/x] \to_C \chi\} = \{\psi[\xi/x] \mid \varphi \to_C \psi\}.$$
(18)

**Proof.** We distinguish cases depending on the shape of  $\varphi$ .

If  $\varphi \neq x$  is atomic then there are no  $\psi$  with  $\varphi \rightarrow_C \psi$ . Because there is also no  $\rightarrow_C$ -successor of  $\varphi[\xi/x] = y[\xi/x] = \varphi$  the claim holds trivially.

The cases where  $\varphi = \varphi_0 \odot \varphi_1$  with  $\odot \in \{\land,\lor\}$ , or  $\varphi = \heartsuit \psi$  with  $\heartsuit \in \{\diamondsuit,\Box\}$  are straightforward.

If  $\varphi = \eta y . \rho$ , then the unique  $\to_C$ -successor of  $\varphi$  is the formula  $\rho[\varphi/y]$ . We distinguish further cases depending on whether y = x. If y = x then we have  $\varphi[\xi/x] = \varphi$ , and this formula has again  $\rho[\varphi/y]$  as its only  $\to_C$ -successor. Because  $x \notin FV(\varphi)$  we also have  $\rho[\varphi/x][\xi/x] = \rho[\varphi/x]$  and thus the claim holds trivially.

If  $y \neq x$  then we find  $\varphi[\xi/x] = \eta y \cdot \rho[\xi/x]$ , and the unique  $\rightarrow_C$ -successor of this formula is its unfolding  $(\rho[\xi/x])[\varphi[\xi/x]/y]$ . For the right hand side of (18), obviously the unique  $\rightarrow_C$ -successor of  $\varphi$  is its unfolding  $\rho[\varphi/y]$ . It is thus left to show that

$$\left(\rho[\xi/x]\right)[\varphi[\xi/x]/y] = \left(\rho[\varphi/y]\right)[\xi/x]. \tag{19}$$

But we have  $BV(\varphi) \subseteq BV(\chi)$  by Proposition 2.42 and  $BV(\chi) \cap FV(\xi) \subseteq \{x\}$  by the tidyness of  $\chi[\xi/x]$ . Thus it follows from  $y \in BV(\varphi)$  and  $y \neq x$  that  $y \notin FV(\xi)$ . Hence (19) follows by Proposition 2.55 — the condition that  $\xi$  is free for x in  $\rho[\varphi/y]$  follows by Proposition 2.42 as well. QED

#### Free subformulas

We now have a closer look at the relation between the sets  $Sf(\xi)$  and  $Cl(\xi)$ . Our first observation concerns the question, which subformulas of a formula also belong to its closure. This brings us to the notion of a *free* subformula.

**Definition 2.57** Let  $\varphi$  and  $\psi$  be  $\mu$ -calculus formulas. We say that  $\varphi$  is a *free* subformula of  $\psi$ , notation:  $\varphi \leq_f \psi$ , if  $\psi = \psi'[\varphi/x]$  for some formula  $\psi'$  such that  $x \in FV(\psi')$  and  $\varphi$  is free for x in  $\psi'$ .

Note that in particular all literals occurring in  $\psi$  are free subformulas of  $\psi$ . The following characterisation is useful. Recall that we write  $\varphi \twoheadrightarrow_C \psi$  if  $\psi \in Cl(\varphi)$ , or equivalently, if there is a trace (possibly of length zero) from  $\varphi$  to  $\psi$ .

**Proposition 2.58** Let  $\varphi$  and  $\psi$  be  $\mu$ -calculus formulas. If  $\psi$  is tidy, then the following are equivalent:

1)  $\varphi \leq f \psi$ ; 2)  $\varphi \leq \psi$  and  $FV(\varphi) \cap BV(\psi) = \emptyset$ ; 3)  $\varphi \leq \psi$  and  $\psi \twoheadrightarrow_C \varphi$ .

**Proof.** We will prove the equivalence of the statements 1) - 3) to a fourth statement, viz.:

4) there is a  $\triangleleft_0$ -chain  $\varphi = \chi_0 \triangleleft_0 \chi_1 \triangleleft_0 \cdots \triangleleft_0 \chi_n = \psi$ , such that no  $\chi_i$  has the form  $\chi_i = \eta y \rho_i$ with  $y \in FV(\varphi)$ .

For the implication 1)  $\Rightarrow$  4), assume that  $\varphi \leq_f \psi$ , then by definition  $\psi$  is of the form  $\psi'[\varphi/x]$  where  $x \in FV(\psi')$  and  $\varphi$  is free for x in  $\psi'$ . But if  $x \in FV(\psi)$ , then it is easy to see that there is a  $\triangleleft_0$ -chain  $x = \chi'_0 \triangleleft_0 \chi'_1 \triangleleft_0 \cdots \triangleleft_0 \chi'_n = \psi'$  such that no  $\chi'_i$  is of the form  $\chi'_i = \lambda x \cdot \rho'$ . Assume for contradiction that one of the formulas  $\chi'_i$  is of the form  $\chi_i = \eta y \cdot \rho_i$  where  $y \in FV(\varphi)$ . Since  $\varphi$  is free for x in  $\psi'$  this would mean that there is a formula of the form  $\lambda x \cdot \chi$  with  $\eta y \cdot \rho_i \leq \lambda x \cdot \chi \leq \psi'$ . However, the only candidates for this would be the formulas  $\chi'_j$  with j > i, and we just saw that these are not of the shape  $\lambda x \cdot \rho'$ . This provides the desired contradiction.

For the opposite implication  $4) \Rightarrow 1$ , assume that there is a  $\triangleleft_0$ -chain  $\varphi = \chi_0 \triangleleft_0 \chi_1 \triangleleft_0 \cdots \triangleleft_0 \chi_n = \psi$  as in the formulation of 4). One may then show by a straightforward induction that  $\varphi \triangleleft_f \chi_i$ , for all  $i \ge 0$ .

For the implication 2)  $\Rightarrow$  4), assume that  $\varphi \leq \psi$  and  $FV(\varphi) \cap BV(\psi) = \emptyset$ . It follows from  $\varphi \leq \psi$  that there is a  $\triangleleft_0$ -chain  $\varphi = \chi_0 \triangleleft_0 \chi_1 \triangleleft_0 \cdots \triangleleft_0 \chi_n = \psi$ . Now suppose for contradiction that one of the formulas  $\chi_i$  would be of the form  $\chi_i = \eta y . \rho_i$  with  $y \in FV(\varphi)$ . Then we would find  $y \in FV(\varphi) \cap BV(\psi)$ , contradicting the assumption that  $FV(\varphi) \cap BV(\psi) = \emptyset$ .

2 - 30

In order to prove the implication  $4) \Rightarrow 3$ , it suffices to show, for any n, that if  $(\chi_i)_{0 \le i \le n}$ is an  $\triangleleft_0$ -chain of length n + 1 such that no  $\chi_i$  has the form  $\chi_i = \eta y . \rho_i$  with  $y \in FV(\chi_0)$ , then  $\chi_n \twoheadrightarrow_C \chi_0$ . We will prove this claim by induction on n. Clearly the case where n = 0 is trivial.

For the inductive step we consider a chain

$$\chi_0 \triangleleft_0 \chi_1 \triangleleft_0 \cdots \triangleleft_0 \chi_n \triangleleft_0 \chi_{n+1}$$

such that no  $\chi_i$  has the form  $\chi_i = \eta y \rho_i$  with  $y \in FV(\chi_0)$ , and we make a case distinction as to the nature of  $\chi_{n+1}$ . Clearly  $\chi_{n+1}$  cannot be an atomic formula.

If  $\chi_{n+1}$  is of the form  $\rho_0 \circledast \rho_1$  with  $\circledast \in \{\land,\lor\}$ , then since  $\chi_n \triangleleft_0 \chi_{n+1}$ , the first formula must be of the form  $\chi_n = \rho_i$  with  $i \in \{0,1\}$ . But since it follows by the induction hypothesis that  $\chi_n \twoheadrightarrow_C \chi_0$ , we obtain from  $\chi_{n+1} \rightarrow_C \chi_n$  that  $\chi_{n+1} \twoheadrightarrow_C \chi_0$  as required. The case where  $\chi_{n+1}$  is of the form  $\heartsuit \rho$  with  $\heartsuit \in \{\diamondsuit, \square\}$  is handled similarly.

This leaves the case where  $\chi_{n+1} = \lambda y . \rho$  is a fixpoint formula. Then since  $\chi_n \triangleleft_0 \chi_{n+1}$  it must be the case that  $\chi_n = \rho$ . Furthermore, it follows from the assumption in 4) that  $y \notin FV(\chi_0)$ . From this it is not so hard to see that

$$\chi_0 \triangleleft_0 \chi_1[\chi_{n+1}/y] \triangleleft_0 \cdots \triangleleft_0 \chi_n[\chi_{n+1}/y]$$

is a  $\triangleleft_0$ -chain to which the induction hypothesis applies. It follows that  $\chi_n[\chi_{n+1}/y] \twoheadrightarrow_C \chi_0$ . From this and the observation that  $\chi_{n+1} \rightarrow_C \chi_n[\chi_{n+1}/y]$  we find that  $\chi_{n+1} \twoheadrightarrow_C \chi_0$  indeed. This finishes the proof of the implication  $4) \Rightarrow 3$ ).

Finally, it follows from Proposition 2.42(1) that  $\psi \twoheadrightarrow_C \varphi$  implies  $FV(\varphi) \cap BV(\psi) \subseteq FV(\psi) \cap FV(\psi) = \emptyset$ . From this the implication 3)  $\Rightarrow$  2) is immediate. QED

As a nice application of the notion of a *free subformula*, the following proposition states that under some mild conditions, the substitution operation  $[\xi/x]$  is in fact injective.

**Proposition 2.59** Let  $\varphi_0, \varphi_1$  and  $\xi$  be formulas such that  $\xi$  is free for x in both  $\varphi_0$  and  $\varphi_1$ , and not a free subformula of either  $\varphi_i$ . Then

$$\varphi_0[\xi/x] = \varphi_1[\xi/x] \text{ implies } \varphi_0 = \varphi_1. \tag{20}$$

**Proof.** We first observe that, with  $\varphi_0, \varphi_1, \xi$  and x as in the statement of the proposition, it holds that

$$\varphi_0[\xi/x] = \varphi_1[\xi/x] \text{ implies that } x \in FV(\varphi_0) \text{ iff } x \in FV(\varphi_1).$$
(21)

This is in fact easy to see: if  $x \in FV(\varphi_0) \setminus FV(\varphi_1)$ , then we would obtain a contradiction from  $\xi \leq_f \varphi_0[\xi/x] = \varphi_1[\xi/x] = \varphi_1$ .

We now turn to (20), which we will prove by a straightforward induction on the complexity of  $\varphi_0$ . Note that by (21) we only need to worry if  $x \in FV(\varphi_0) \cap FV(\varphi_1)$ ; if this is not the case then (20) holds trivially.

In particular, this means that the base step of the inductive proof of (20) is reduced to the case where  $\varphi_0 = \varphi_1 = x$ , so that (20) holds trivially.

#### Lectures on the modal $\mu$ -calculus

For the inductive step we first consider the case where  $\varphi_0$  is of the form  $\psi_0 \wedge \chi_0$ . Then we obtain  $\varphi_0[\xi/x] = \psi_0[\xi/x] \wedge \chi_0[\xi/x]$ . But if  $\varphi_1[\xi/x] = \psi_0[\xi/x] \wedge \chi_0[\xi/x]$  and  $\xi \not \leq_f \varphi_1$ , it must be the case that  $\varphi_1$  is of the form  $\varphi_1 = \psi_1 \wedge \chi_1$ , with  $\psi_1[\xi/x] = \psi_0[\xi/x]$  and  $\chi_1[\xi/x] = \chi_0[\xi/x]$ . By the induction hypothesis we obtain  $\psi_0 = \psi_1$  and  $\chi_0 = \chi_1$ , so that  $\varphi_0 = \varphi_1$  indeed.

The cases for disjunction and the modal operators are very similar to this, so we omit the details.

This leaves the case where  $\varphi_0$  is of the form  $\varphi_0 = \eta y.\psi_0$ . Restricting to the case where  $x \in FV(\varphi_0) \cap FV(\varphi_1)$  we may assume that x and y are distinct variables, so we have  $\varphi_0[\xi/x] = \eta y.\psi_0[\xi/x]$ . But it follows from  $\eta y.\psi_0[\xi/x] = \varphi_1[\xi/x]$  and  $\xi \not\leq_f \varphi_1$ , that  $\varphi_1$  must be of the form  $\varphi_1 = \eta y.\psi_1$  for some formula  $\psi_1$  with  $\psi_0[\xi/x] = \psi_1[\xi/x]$ . Thus the inductive hypothesis yields that  $\psi_0 = \psi_1$ , which immediately implies that  $\varphi_0 = \varphi_1$  as required. QED

#### The expansion map

The most important observation here concerns the existence of a surjective map from  $Sf(\xi)$  to  $Cl(\xi)$ , at least for a clean formula  $\xi$ .

Recall that, given a clean formula  $\xi$ , we define the *unfolding order*  $\leq_{\xi}$  on the set  $BV(\xi)$  by putting  $x \leq_{\xi} y$  if  $\delta_x \leq \delta_y$ ; let  $\triangleleft_{\xi}$  be the strict (irreflexive) version of this order, that is,  $x \triangleleft_{\xi} y$  if  $\delta_x$  is a proper subformula of  $\delta_y$ .

**Definition 2.60** Writing  $BV(\xi) = \{x_1, \ldots, x_n\}$ , where we may assume that i < j if  $x_i \triangleleft_{\xi} x_j$ , we define the *expansion*  $\exp_{\xi}(\varphi)$  of a subformula  $\varphi$  of  $\xi$  as:

$$\exp_{\xi}(\varphi) := \varphi[\eta_{x_1} x_1 . \delta_{x_1} / x_1] \dots [\eta_{x_n} x_n . \delta_{x_n} / x_n].$$

That is, we substitute first the lowest ranking variable  $x_1$  by  $\eta_{x_1}x_1.\delta_{x_1}$  in  $\varphi$ ; in the resulting formula, we substitute  $x_2$  by  $\eta_{x_2}x_2.\delta_{x_2}$ , etc. If no confusion is likely we write  $\exp(\varphi)$  instead of  $\exp_{\varepsilon}(\varphi)$ .

Without proof we mention the following result.

**Proposition 2.61** Let  $\xi \in \mu$ ML be a clean formula and S a pointed Kripke structure. Then for all subformulas  $\varphi \leq \xi$  and all states s in S we have

$$(\varphi, s) \in \operatorname{Win}_{\exists}(\mathcal{E}(\xi, \mathbb{S})) \text{ iff } \mathbb{S}, s \Vdash_g \exp_{\xi}(\varphi).$$

The proposition below states that, for a clean formula  $\xi$ , the expansion map is a surjection from its set of subformulas to its closure. As an immediate corollary we obtain that the size of  $Cl(\xi)$  is *bounded* by that of  $Sf(\xi)$ .

**Proposition 2.62** Let  $\xi$  be a clean  $\mu$ ML-formula. Then

$$Cl(\xi) = \{ \exp_{\xi}(\varphi) \mid \varphi \leqslant \xi \}.$$
(22)

**Proof.** For the time being we confine ourselves to a brief sketch. For the inclusion  $\subseteq$  it suffices to show that the set  $\{\exp_{\xi}(\varphi) \mid \varphi \leq \xi\}$  has the relevant closure properties. This is a fairly routine proof. For the opposite inclusion it suffices to prove that  $\exp_{\xi}(\varphi) \in Cl(\xi)$ , for every  $\varphi \in Sf(\xi)$ , which can be done by a straightforward induction. QED

#### 2.8 Disjunctive formulas

In the theory of the modal  $\mu$ -calculus, a fundamental role is played by the so-called *disjunc*tive formulas. These are built using the cover modality discussed in Section 1.7, and, as discussed there in the setting of basic modal logic, characterised by a severely restricted use of conjunctions.

▶ For the time being we confine attention to the monomodal case

We first introduce the full language of the nabla-based version of the modal  $\mu$ -calculus. This is simply the extension of the language  $ML_{\nabla}$  with fixpoint operators. Recall that in this language we work with the *finitary* versions of conjunction and disjunction.

**Definition 2.63** The formulas of the language  $\mu ML_{\nabla}$  are given by the following grammar:

$$\varphi ::= p \mid \overline{p} \mid \bigvee \Phi \mid \land \Phi \mid \nabla \Phi \mid \mu x \varphi \mid \nu x \varphi$$

where p and x are propositional variables,  $\Phi \subseteq_{\omega} \mu \mathsf{ML}_{\nabla}$ , and the formation of the formulas  $\eta x \varphi$  is subject to the proviso that there are no occurrences of the literal  $\overline{x}$  in  $\varphi$ .

As in the basic (fixpoint-free) case, the only conjunctions that we allow in a disjunctive formula are of the form  $\alpha \bullet \Phi$ . The latter formula stands for the conjunction  $(\bigwedge \alpha) \land \nabla \Phi$ , where  $\alpha$  and  $\Phi$  are finite sets of, respectively, literals and disjunctive formulas. Based on our discussion in the fixpoint-free case, one might suggest to define disjunctive formulas by means of the following grammar:

$$\varphi ::= \top \mid \bigvee \Phi \mid \alpha \bullet \Phi \mid \mu x \varphi \mid \nu x \varphi,$$

where  $\alpha$  is an arbitrary set of literals, and we have the usual positivity constraint on the formation of fixpoint formulas  $\eta x \varphi$ . Recall that in this set-up, every conjunction  $\bigwedge \alpha$  of literals, though strictly speaking not disjunctive, can be represented by the disjunctive formula

$$\bigwedge \alpha \equiv \alpha \bullet \{\top\} \lor \alpha \bullet \varnothing.$$

The question is, however, whether we should allow *bound* variables to occur to the left of a bullet conjunction: such variables represent their unfoldings, and since these unfoldings may be much more complex than literals, effectively we risk letting in nontrivial conjunctions through the back door. For instance, given a clean ambient formula  $\xi$ , a subformula of the form, say,  $\{x, y\} \bullet \nabla \Phi$  with x and y bound, would correspond to the non-disjunctive formula  $\delta_x \wedge \delta_y \wedge \nabla \Phi$ .

effectively we are letting in nontrivial conjunctions through the back door.

For this reason we will make an a priori distinction between free and bound variables, the idea being that the free variables can only occur (positively or negatively) among the literals that occur to the left of the bullet conjunctions, while the bound variables can occur anywhere else but not there. It also turns out that we do not need to take  $\top$  as a primitive disjunctive formulas, see Example 2.65 below.

Lectures on the modal  $\mu$ -calculus

**Definition 2.64** Let P be a finite set of propositional variables. To define the set  $\mu DML(P)$  of *(monomodal) disjunctive formulas in* P we start with the expressions given by the following grammar:

$$\varphi ::= x \mid \bigvee \Phi \mid \alpha \bullet \Phi \mid \mu x \varphi \mid \nu x \varphi$$

where x is a propositional variable not in P,  $\Phi$  is a finite set of formulas from this grammar, and  $\alpha$  is a finite set of literals over P; furthermore, the formulas  $\mu x \varphi$  and  $\nu x \varphi$  can only be formed if  $\overline{x}$  does not occur in  $\varphi$ .

The set  $\mu DML(P)$  of disjunctive formulas over P consists of all expressions  $\xi$  that meet this pattern and satisfy the condition that  $FV(\xi) \subseteq P$ . We let  $\mu DML$  be the set of formulas that are disjunctive in some set P, and we call a formula disjunctive if it belongs to this set  $\mu DML$ .

#### ▶ Note that disjunctive formulas are tidy.

In practice we will often pretend that atomic formulas, and in fact all propositional formulas in disjunctive normal form, are disjunctive. This can be justified as follows.

**Example 2.65** As in the basic case, the constant  $\perp$  can be seen as an abbreviation of the disjunctive formula  $\bigvee \emptyset$ . Different from the basic case, however, we can do without the constant  $\top$  as a primitive constant either, since the presence of the greatest fixpoint operator enables us to write

$$\top \equiv \nu x \, (\emptyset \bullet \emptyset \lor \emptyset \bullet \{x\}).$$

A different way of representing the boolean constants as disjunctive formulas would be via the equivalences  $\perp \equiv \mu x.x$  and  $\top \equiv \nu x.x$ ; these representations are simpler indeed, but have the disadvantage that they are nor guarded.

As we saw in our discussion in the basic (fixpoint-free) case, literals do not qualify as disjunctive formulas, but any literal  $\ell$  is equivalent to a disjunctive formula as well:

$$\ell \equiv \{\ell\} \bullet \{\top\} \lor \{\ell\} \bullet \varnothing.$$

Slightly extending this example, we may represent any finite conjunction of literals by a disjunctive formula via the equivalence  $\bigwedge \alpha \equiv \alpha \bullet \{\top\} \lor \alpha \bullet \emptyset$  which we already displayed above. Finally based on this we use the equivalence

$$\bigvee \left\{ \bigwedge \alpha_i \mid i \in I \right\} \equiv \bigvee \left\{ \alpha_i \bullet \{\top\} \lor \alpha_i \bullet \emptyset \mid i \in I \right\}.$$

and in practice pretend that any propositional formula in disjunctive normal form is disjunctive in the current sense as well:  $\times$ 

**Example 2.66** Another example of a disjunctive formulas is  $\mu x \left(\{p, \overline{q}\} \bullet \{x, \nu y (\{p\} \bullet \{x \lor y\})\}\right)$ , but not its subformula  $\{p, \overline{q}\} \bullet \{x, \nu y (\{p\} \bullet \{x \lor y\})\}$  (since in the latter formula x is free, and hence, it may not appear in the set to the right of either of the bullet conjunctions). A final example of a non-disjunctive formula is  $\mu x \left(\{\overline{p}, \overline{q}\} \bullet \{x, \nu y (\{p, x\} \bullet \{x, \top\})\}\right)$  (here the subformula  $\{p, x\} \bullet \{x, \top\}$  is not admissible since x, being a bound variable, may not occur in the set to the left of the bullet conjunction).

Turning to the semantics of disjunctive formulas, below we introduce the *evaluation game* for this language. For this definition we recall that a relation  $Z \subseteq S \times S'$  is *full* on some pair  $(U, U') \in \wp(S) \times \wp(S')$  if  $U \subseteq \text{Dom}(Z)$  and  $U' \subseteq Ran(Z)$ , or, in other words, if every  $u \in U$  is related by Z to some  $u' \in U'$ , and vice versa.

Position	Player	Admissible moves
$(\bigvee \Phi, s)$	Э	$\{(\varphi,s) \mid \varphi \in \Phi\}$
$(\alpha \bullet \Phi, s)$	A	$\{(\ell,s) \mid \ell \in \alpha\} \cup \{(\nabla \Phi,s)\}$
$(p,s)$ with $p \in FV(\xi)$ and $s \in V(p)$	A	Ø
$(p,s)$ with $p \in FV(\xi)$ and $s \notin V(p)$	E	Ø
$(\overline{p}, s)$ with $p \in FV(\xi)$ and $s \in V(p)$	E	Ø
$(\overline{p}, s)$ with $p \in FV(\xi)$ and $s \notin V(p)$	A	Ø
$( abla \Phi, s)$	E	$\{Z \subseteq \Phi \times R[s] \mid Z \text{ is full on } \Phi \text{ and } R[s]\}$

$(\eta_x x. \varphi, s)$	_	$\{(\varphi[\eta x\varphi/x],s)\}$

Table 6: Evaluation game for disjunctive formulas (closure version)

**Definition 2.67** The positions and admissible moves of the evaluation game for clean disjunctive formulas are given in Table 11. The winning conditions are as in the evaluation games for arbitrary  $\mu$ ML-formulas.

Most of the moves of the evaluation game speak for themselves (given the interpretation of  $\alpha \bullet \Phi$  as  $(\bigwedge \alpha) \land \nabla \Phi$ ).

What makes the evaluation game for disjunctive formulas special is the kind of move that  $\exists$  makes at a position of the form  $(\nabla \Phi, s)$ : here she picks a relation  $Z \subseteq \mu \text{DML}(\mathsf{P}) \times S$  of witnesses (with the requirement that Z is full on  $\Phi$  and R[s]). Such a binary relation Z thus forms a new type of position, which is not a formula-state pair, but rather, a set of such pairs. These relational positions all belong to  $\forall$ , and his task at a position Z is simply to pick a witness from Z, that is, a pair  $(\psi, t)$  in Z. Of course this is in accordance with the semantic meaning of the cover modality.

In the following definition and propositions we isolate the key game-theoretic property of disjunctive formulas. Recall that, for a given strategy f in some evaluation game  $\mathcal{E}(\xi, \mathbb{S})$ starting at position  $(\xi, s)$ , we call a position  $(\varphi, t)$  f-reachable if there is some f-guided match in which the position  $(\varphi, t)$  is reached. We say that the state t is f-reachable if there is some formula  $\varphi$  such that the position  $(\varphi, t)$  is f-reachable.

**Definition 2.68** Let  $\xi$  be a disjunctive formula, and let  $(\mathbb{S}, s)$  be a pointed model.

A strategy f for  $\exists$  in the evaluation game  $\mathcal{E}(\xi, \mathbb{S})@(\xi, s)$  is called *separating* if at every f-reachable position of the form  $(\nabla \Phi, s)$ , f picks a relation  $Z \subseteq \Phi \times R[s]$  such that for every  $t \in R[s]$  there is exactly one  $\varphi \in \Phi$  such that  $(\varphi, t) \in Z$ .

A strategy f for  $\exists$  in  $\mathcal{E}(\xi, \mathbb{S})@(\xi, s)$  is *thin* if for every  $t \in S$  there is at most one formula  $\varphi$  of the form  $\alpha \bullet \Phi$  such that  $(\varphi, t)$  is f-reachable.

If f is a thin strategy which is winning for  $\exists \text{ in } \mathcal{E}(\xi, \mathbb{S})@(\xi, s)$  then we say that  $\xi$  is strongly satisfied in  $\mathbb{S}$  at s, notation:  $\mathbb{S}, s \Vdash_s \xi$ .

The name 'separating' is chosen for obvious reasons: if, at position  $(\nabla \Phi, s)$ ,  $\exists$  picks a functional relation Z, she effectively separates the elements of  $\Phi$  from one another, in the sense that there are no two witnesses  $(\varphi, t), (\varphi', t)$  in Z with  $\varphi \neq \varphi'$ . It is easy to see that separating winning strategies on tree models are thin.

**Proposition 2.69** Let  $\xi$  be a disjunctive formula, and let  $(\mathbb{S}, s)$  be a tree model. If f is a separating winning strategy for  $\exists$  in  $\mathcal{E}(\xi, \mathbb{S})@(\xi, s)$  then f is thin.

Strong satisfaction is a very strong kind of satisfaction indeed, and in later chapters we will use it as a key model-theoretic tool. The thinness of separating strategies on tree models will turn out to be an extremely useful property. The fundamental model-theoretic property of disjunctive formulas is that without loss of generality we may always assume that winning strategies are separating, provided that we allow ourselves to move to a bisimilar model.

**Theorem 2.70** Let  $\xi$  be a disjunctive formula, and let  $(\mathbb{S}, s)$  be a pointed model. Then the following are equivalent:

- 1)  $\mathbb{S}, s \Vdash \xi$ 2)  $\mathbb{S}', s' \Vdash_s \xi$  for some pointed tree model such that  $\mathbb{S}, s \leftrightarrow \mathbb{S}', s'$ .
- ▶ The proof of this theorem, which hinges on the semantics of the cover modality, will be given later.

Since the cover modality can be expressed in terms of the box and diamond operators, it is obvious that  $\mu$ DML can be thought of as a *fragment* of the full language of the  $\mu$ -calculus. One of the fundamental theorems in the theory of the modal  $\mu$ -calculus is that  $\mu$ DML has the *same* expressive power as the full language. This equivalence is in fact effective, as stated by the next theorem.

**Theorem 2.71** There are effective procedures transforming an arbitrary formula  $\varphi \in \mu ML$ into an equivalent disjunctive formula, and vice versa. As a corollary, the languages  $\mu ML$ ,  $\mu ML_{\nabla}$  and  $\mu DML$  all have the same expressive power.

The *proof* of Theorem 2.71 will be given in a later chapter.

# Notes

The modal  $\mu$ -calculus was introduced by D. Kozen [10]. Its game-theoretical semantics goes back to at least Emerson & Jutla [6] (who use alternating automata as an intermediate step). As far as we are aware, the bisimulation invariance theorem, with the associated tree model property, is a folklore result. The bounded tree model property is due to Kozen & Parikh [11].

There are various ways to make the notion of alternation depth precise; we work with the most widely used definition, which originates with Niwiński [16].

# Exercises

**Exercise 2.1** Express in words the meaning of the following  $\mu$ -calculus formulas:

- (a)  $\nu x.\mu y.(p \wedge \Box x) \vee (\overline{p} \wedge \Box y)$
- (b)  $\nu x.\mu y.(p \land \Diamond x) \lor (q \land \Diamond y)$
- (c)  $\mu x.\nu y.(p \land \Diamond x) \lor (q \land \Diamond y)$

**Exercise 2.2 (defining modal**  $\mu$ -formulas) Give a modal  $\mu$ -formula  $\varphi(p,q)$  such that for all transition systems S, and all states  $s_0$  in S:

 $\mathbb{S}, s_0 \Vdash_g \varphi(p,q)$  iff there is a path  $s_0 R s_1 \dots R s_n$   $(n \ge 0)$  such that  $\mathbb{S}, s_n \Vdash_g p$ and  $\mathbb{S}, s_i \Vdash_q q$  for all i with  $0 \le i < n$ .

## Exercise 2.3 (characterizing winning strategies)

A board is a structure  $\mathbb{B} = \langle B_0, B_1, E \rangle$  such that  $B_0 \cap B_1 = \emptyset$  and  $E \subseteq B^2$ , where  $B = B_0 \uplus B_1$ is a set of objects called *positions*. A *match* on  $\mathbb{B}$  consists of the *players* 0 and 1 moving a token from one position to another, following the edge relation E. Player i is supposed to move the token when it is situated on a position in  $B_i$ . Suppose in addition that B is also partitioned into green and red positions,  $B = G \uplus R$ .

We will use a modal language to describe this structure, with the modalities being interpreted by the edge relation E, the proposition letter  $p_0$  and r referring to the positions belonging to player 0, and the red positions, respectively. That is,  $V(p_0) = B_0$  and V(r) = R.

(a) Consider the game where player 0 wins as soon as the token reaches a green position. (That is, all infinite matches are won by player 1. Player 0 wins if player 1 gets stuck, or if the token reaches a green position; player 1 wins a finite match if player 0 gets stuck.) Show that the formula  $\varphi_a = \mu x. \overline{r} \lor (p_0 \land \Diamond x) \lor (\overline{p}_0 \land \Box x)$  characterizes the winning positions for player 0 in this game, in the sense that for any position  $b \in B$ , we have

 $\mathbb{B}, V, b \Vdash_g \varphi$  iff player 0 has a w.s. in the game starting at position b.

# 2-36

(b) Now consider the game where player 0 wins if she manages to reach a green position *infinitely often*. (More precisely, infinite matches are won by 0 iff a green position is reached infinitely often; finite matches are lost by a player is he/she gets stuck.) Give a formula  $\varphi_b$  that characterizes the winning positions in this game.

Exercise 2.4 (characterizing fairness) Let  $D = \{a, b\}$  be the set of atomic actions, and consider the following formula  $\xi$ , with subformulas as indicated:

$$\xi = \nu x.\mu y.\nu z.\underbrace{\Box_a x}_{\alpha_1} \wedge \underbrace{(\Box_a \bot \lor \Box_b y)}_{\alpha_2} \wedge \underbrace{\Box_b z}_{\alpha_3}$$

Fix an LTS  $\mathbb{S} = (S, R_a, R_b, V)$ . We say that the transition *a* is *enabled* at state *s* of  $\mathbb{S}$  if  $\mathbb{S}, s \Vdash_g \diamondsuit_a \top$ .

Show that  $\xi$  expresses some kind of *fairness* condition, i.e., the absence of a path starting at s on which a is enabled infinitely often, but executed only finitely often. More precisely, prove that  $\mathbb{S}, s \Vdash_g \xi$  iff there is *no* path of the form  $s_0 \xrightarrow{d_0} s_1 \xrightarrow{d_1} s_2 \cdots$  such that  $s = s_0$ ,  $d_i \in \{a, b\}$  for all i, a is enabled at  $s_i$  for infinitely many i, but  $d_i = a$  for only finitely many i.

**Exercise 2.5 (filtration)** Recall that, given a finite, closed set of formulas  $\Sigma$  and a model  $\mathbb{S} = (S, R, V)$ , we say that a model  $\mathbb{S}' = (S', R', V')$  is a *filtration* of  $\mathbb{S}$  through  $\Sigma$  if there is a surjective map  $f : S \to S'$  such that:

- a) for all proposition letters  $p \in \Sigma$ :  $u \in V(p)$  iff  $f(u) \in V'(p)$ .
- b) uRv implies f(u)R'f(v)
- c) if  $\Diamond \varphi \in \Sigma$  and f(u)R'f(v), then  $\mathbb{S}, v \Vdash_g \varphi$  implies  $\mathbb{S}, u \Vdash_g \Diamond \varphi$
- d) f(u) = f(v) if and only if u and v satisfy precisely the same formulas in  $\Sigma$ .

Say that a formula  $\xi$  of the  $\mu$ -calculus *admits filtration* if, for every model  $\mathbb{S}$ , there is a finite set of formulas  $\Sigma$  containing  $\xi$ , and a filtration  $\mathbb{S}'$  of  $\mathbb{S}$  through  $\Sigma$  such that  $\mathbb{S}', f(s) \Vdash_g \varphi$  iff  $\mathbb{S}, s \Vdash_g \varphi$ , for each s in  $\mathbb{S}$  and each  $\varphi \in \Sigma$ .

Prove that the formula  $\mu x.\Box x$  does not admit filtration.

**Exercise 2.6** We write  $\varphi \models \psi$  to denote that  $\psi$  is a *local consequence* of  $\varphi$ , that is, if for all pointed Kripke models  $(\mathbb{S}, s)$  it holds that  $\mathbb{S}, s \Vdash_g \varphi$  implies  $\mathbb{S}, s \Vdash_g \psi$ .

- (a) Show that  $\mu x.\nu y. \alpha(x,y) \models \nu y.\mu x. \alpha(x,y)$ , for all formulas  $\alpha$ .
- (b) Show that  $\mu x.\mu y. \alpha(x, y) \equiv \mu y.\mu x. \alpha(x, y)$ , for all formulas  $\alpha$ .
- (c) Show that  $\mu x.(x \vee \gamma(x)) \wedge \delta(x) \models \mu x.\gamma(x) \wedge \delta(x)$ , for all formulas  $\gamma, \delta$ .

**Exercise 2.7 (boolean**  $\mu$ -calculus) Show that the least and greatest fixpoint operators do not add expressive power to classical propositional logic, or, in other words, that the modality-free fragment of the modal  $\mu$ -calculus is expressively equivalent to classical propositional logic. (Hint: use Exercise 2.6(c).)

**Exercise 2.8 (co-induction)** Let  $\varphi, \psi$  be any two clean formulas of the modal  $\mu$ -calculus such that  $\psi$  is free for x in  $\varphi$ ; it will also be convenient to assume that  $\psi$  is not a subformula of  $\varphi$ . Show by a game semantic argument that the following so-called 'co-induction principle' holds for greatest fixpoints: if  $\psi \models \varphi[\psi/x]$ , then  $\psi \models \nu x.\varphi$  also. Here we write ' $\models$ ' for the local consequence relation, as in Exercise 2.6.

#### Exercise 2.9 (traces)

(a) Let  $\xi = \eta x \chi$  be a tidy fixpoint formula, and let  $\varphi$  be a subformula of its unfolding. Show that either  $\varphi \leq \xi$  or  $\xi \leq \varphi$ .

Hint: prove that every subformula  $\alpha \leq \chi$  satisfies the following:

if 
$$\varphi \leq \alpha[\xi/x]$$
 then  $\varphi \leq \xi$  or  $\xi \leq \varphi$ .

- (b) Let  $\tau : \xi_n \to_C \ldots \to_C \xi_1$  be a finite trace of tidy formulas. Show that there is a unique  $\xi \in \{\xi_1, \ldots, \xi_n\}$  such that  $\xi \leq \xi_i$ , for all *i*. Moreover, if  $\xi_1$  is a fixpoint formula then so is  $\xi$ .
- (c) Let  $\tau$  be an infinite trace of tidy formulas, and let  $Inf(\tau)$  be the set of formulas that occur infinitely often on  $\tau$ . Show that there is a unique formula  $\xi \in Inf(\tau)$  which is a subformula of every formula in  $Inf(\tau)$ . Furthermore, prove that  $\xi$  is a fixpoint formula.

Exercise 2.10 (injectivity of substitution) Prove Proposition 2.59.

# 3 Fixpoints

The game-theoretic semantics of the modal  $\mu$ -calculus introduced in the previous chapter has some attractive characteristics. It is intuitive, relatively easy to understand, and, as we shall see further on, it can be used to prove some important properties of the formalism. However, it has some drawbacks as well. For instance, the evaluation games of the previous chapter have only been defined for formulas that are either clean or tidy. The game semantics can be extended to arbitrary formulas but this will make the game somewhat more involved, in particular if we want to define evaluation games for formulas that are not in negation normal form.

Furthermore, the game-theoretical semantics is not *compositional*; that is, the meaning of a formula is not defined in terms of the meanings of its subformulas. These shortcomings vanish in the *algebraic semantics* that we are about to introduce. In order to define this term, we first consider an example.

**Example 3.1** Recall that in Example 2.1, we informally introduced the formula  $\mu x.p \lor \diamondsuit_d x$  as the smallest fixpoint or solution of the 'equation'  $x \equiv p \lor \diamondsuit_d x$ .

To make this intuition more precise, we have to look at the formula  $\delta = p \lor \diamond_d x$  as an operation. The idea is that the value (that is, the extension) of this formula is a function of the value of x, provided that we keep the value of p constant. Varying the value of x boils down to considering 'x-variants' of the valuation V of  $\mathbb{S} = \langle S, R, V \rangle$ . Let, for  $X \subseteq S$ ,  $V[x \mapsto X]$  denote the valuation that is exactly like V apart from mapping x to X, and let  $\mathbb{S}[x \mapsto X]$  denote the x-variant  $\langle S, R, V[x \mapsto X] \rangle$  of  $\mathbb{S}$ . Then  $[\![\delta]\!]^{\mathbb{S}[x \mapsto X]}$  denotes the extension of  $\delta$  in this x-variant. It follows from this that the formula  $\delta$  induces the following function  $\delta_x^{\mathbb{S}}$  on the power set of S:

$$\delta_x^{\mathbb{S}}(X) := \llbracket \delta \rrbracket^{\mathbb{S}[x \mapsto X]}.$$

In our example we have

$$\delta_x^{\mathbb{S}}(X) = V(p) \cup \langle R \rangle(X).$$

Now we can make precise why  $\mu x.p \lor \diamondsuit_d x$  is a fixpoint formula: its extension, the set  $[\![\mu x.p \lor \diamondsuit_d x]\!]$ , is a fixpoint of the map  $\delta_x^{\mathbb{S}}$ :

$$\llbracket \mu x.p \lor \diamondsuit_d x \rrbracket = V(p) \cup \langle R \rangle (\llbracket \mu x.p \lor \diamondsuit_d x \rrbracket).$$

In fact, as we shall see in this chapter, the formulas  $\mu x.p \lor \diamond_d x$  and  $\nu x.p \lor \diamond_d x$  are such that their extensions are the *least* and *greatest* fixpoints of the map  $\delta_x^{\mathbb{S}}$ , respectively.

It is worthwhile to discuss the theory of fixpoint operators at a more general level than that of modal logic. Before we turn to the definition of the algebraic semantics of the modal  $\mu$ -calculus, we first discuss the general fixpoint theory of monotone operations on complete lattices.

# 3.1 General fixpoint theory

Basics

In this chapter we assume some familiarity<sup>2</sup> with partial orders and lattices (see Appendix A).

**Definition 3.2** Let  $\mathbb{P}$  and  $\mathbb{P}'$  be two partial orders and let  $f: P \to P'$  be some map. Then f is called *monotone* or *order preserving* if  $f(x) \leq f(y)$  whenever  $x \leq y$ , and *antitone* or *order reversing* if  $f(x) \geq f(y)$  whenever  $x \leq y$ .

**Definition 3.3** Let  $\mathbb{P} = \langle P, \leq \rangle$  be a partial order, and let  $f : P \to P$  be some map. Then an element  $p \in P$  is called a *prefixpoint* of f if  $f(p) \leq p$ , a *postfixpoint* of f if  $p \leq f(p)$ , and a *fixpoint* if f(p) = p. The sets of prefixpoints, postfixpoints, and fixpoints of f are denoted respectively as PRE(f), POS(f) and FIX(f).

In case the set of fixpoints of f has a least (respectively greatest) member, this element is denoted as LFP.f (GFP.f, respectively). These least and greatest fixpoints may also be called *extremal fixpoints*.

The following theorem is a celebrated result in fixpoint theory.

**Theorem 3.4 (Knaster-Tarski)** Let  $\mathbb{C} = \langle C, \bigvee, \bigwedge \rangle$  be a complete lattice, and let  $f : C \to C$  be monotone. Then f has both a least and a greatest fixpoint, and these are given as

$$LFP.f = \bigwedge PRE(f), \tag{23}$$

$$GFP.f = \bigvee POS(f). \tag{24}$$

**Proof.** We will only prove the result for the least fixpoint, the proof for the greatest fixpoint is completely analogous.

Define  $q := \bigwedge \operatorname{PRE}(f)$ , then we have that  $q \leq x$  for all prefixpoints x of f. From this it follows by monotonicity that  $f(q) \leq f(x)$  for all  $x \in \operatorname{PRE}(f)$ , and hence by definition of prefixpoints,  $f(q) \leq x$  for all  $x \in \operatorname{PRE}(f)$ . In other words, f(q) is a lower bound of the set  $\operatorname{PRE}(f)$ . Hence, by definition of q as the greatest such lower bound, we find  $f(q) \leq q$ , that is, q itself is a prefixpoint of f.

It now suffices to prove that  $q \leq f(q)$ , and for this we may show that f(q) is a prefixpoint of f as well, since q is by definition a lower bound of the set of prefixpoints. But in fact, we may show that f(y) is a prefixpoint of f for every prefixpoint y of f — by monotonicity of fit immediately follows from  $f(y) \leq y$  that  $f(f(y)) \leq f(y)$ . QED

Another way to obtain least and greatest fixpoints is to *approximate* them from below and above, respectively.

**Definition 3.5** Let  $\mathbb{C} = \langle C, \bigvee, \bigwedge \rangle$  be a complete lattice, and let  $f : C \to C$  be some map. Then by ordinal induction we define the following maps on C:

. . . .

<sup>&</sup>lt;sup>2</sup>Readers lacking this background may take abstract complete lattices to be concrete power set algebras.

where  $\lambda$  denotes an arbitrary limit ordinal.

**Proposition 3.6** Let  $\mathbb{C} = \langle C, \bigvee, \bigwedge \rangle$  be a complete lattice, and let  $f : C \to C$  be monotone. Then f is inductive, that is,  $f^{\alpha}_{\mu}(\bot) \leq f^{\beta}_{\mu}(\bot)$  for all ordinals  $\alpha$  and  $\beta$  such that  $\alpha < \beta$ .

**Proof.** We leave this proof as an exercise to the reader.

Given a set C, we let |C| denote its cardinality or size.

**Corollary 3.7** Let  $\mathbb{C} = \langle C, \bigvee, \bigwedge \rangle$  be a complete lattice, and let  $f : C \to C$  be monotone. Then there is some  $\alpha$  of size at most |C| such that LFP. $f = f^{\alpha}_{\mu}(\bot)$ .

**Proof.** By Proposition 3.6, f is inductive, that is,  $f^{\alpha}_{\mu}(\perp) \leq f^{\beta}_{\mu}(\perp)$  for all ordinals  $\alpha$  and  $\beta$  such that  $\alpha < \beta$ . It follows from elementary set theory that there must be two ordinals  $\alpha, \beta$  of size at most |C| such that  $f^{\alpha}_{\mu}(\perp) = f^{\beta}_{\mu}(\perp)$ . From the definition of the approximations it then follows that there must be an ordinal  $\alpha$  such that  $f^{\alpha}_{\mu}(\perp) = f^{\alpha+1}_{\mu}(\perp)$ , or, equivalently,  $f^{\alpha}_{\mu}(\perp)$  is a fixpoint of f. To show that it is the *smallest* fixpoint, one may prove that  $f^{\beta}_{\mu}(\perp) \leq \text{LFP}.f$  for every ordinal  $\beta$ . This follows from a straightforward ordinal induction. QED

**Definition 3.8** Let  $\mathbb{C} = \langle C, \bigvee, \bigwedge \rangle$  be a complete lattice, and let  $f : C \to C$  be monotone. The least ordinal  $\alpha$  such that  $f^{\alpha}_{\mu}(\bot) = f^{\alpha+1}_{\mu}(\bot)$  is called the *unfolding ordinal* of f.

# **3.2** Boolean algebras

In the special case that the complete lattice is in fact a (complete) *boolean algebra*, there is more to be said.

# Dual maps

In the case of monotone maps on complete boolean algebras, the least and greatest fixed points become interdefinable, using the notion of (boolean) *duals* of maps.

**Definition 3.9** A *complete* boolean algebra is a structure  $\mathbb{B} = \langle B, \bigvee, \bigwedge, -\rangle$  such that  $\langle B, \bigvee, \bigwedge\rangle$  is a complete lattice and  $\langle B, \lor, \land, -, \bot, \top\rangle$  is a boolean algebra, where  $\lor$  and  $\land$  are the binary versions of  $\bigvee$  and  $\bigwedge$ , respectively, and  $\bot := \bigvee \emptyset, \top := \bigwedge \emptyset$ .

In a boolean algebra  $\mathbb{B}$ , the complementation operation  $-: B \to B$  is an antitone (orderreversing) map such that  $x \land -x = \bot$  and  $x \lor -x = \top$  for all  $x \in B$ . If  $\mathbb{B}$  is complete it holds that  $-\bigvee X = \bigwedge \{-x \mid x \in X\}$  and  $-\bigwedge X = \bigvee \{-x \mid x \in X\}$ .

**Definition 3.10** Let  $\mathbb{B} = \langle B, \bigvee, \bigwedge, - \rangle$  be a complete boolean algebra. Given a map  $f : B \to B$ , the function  $f^{\partial} : B \to B$  given by

$$f^{\partial}(b) := -f(-b).$$

is called the *(boolean)* dual of f.

 $\triangleleft$ 

QED

**Proposition 3.11** Let  $\mathbb{B} = \langle B, \bigvee, \bigwedge, - \rangle$  be a complete boolean algebra, and let  $g : B \to B$  be monotone. Then  $g^{\partial}$  is monotone as well,  $(g^{\partial})^{\partial} = g$ , and

**Proof.** We only prove that  $LFP.g^{\partial} = -GFP.g$ , leaving the other parts of the proof as exercises to the reader.

First, note that by monotonicity of  $g^{\partial}$ , the Knaster-Tarski theorem gives that

LFP.
$$g^{\partial} = \bigwedge \operatorname{PRE}(g^{\partial}).$$

But as a consequence of the definitions, we have that

$$b \in \operatorname{PRE}(g^{\partial}) \iff -b \in \operatorname{POS}(g).$$

From this it follows that

$$LFP.g^{\partial} = \bigwedge \{b \mid -b \in POS(g)\} \\ = \bigwedge \{-a \mid a \in POS(g)\} \\ = -\bigvee POS(g) \\ = -GFP.g$$

which finishes the proof of the Theorem.

Further on we will see that Proposition 3.11 allows us to define negation as an abbreviated operator in the modal  $\mu$ -calculus.

#### Games

In case the boolean algebra in question is in fact a *power set algebra*, a nice game-theoretic characterization of least and greatest fixpoint operators can be given.

**Definition 3.12** Let S be some set and let  $F : \wp(S) \to \wp(S)$  be a monotone operation. Consider the *unfolding games*  $\mathcal{U}^{\mu}(F)$  and  $\mathcal{U}^{\nu}(F)$ . The positions and admissible moves of these two graph games are the same, see Table 7.

Position	Player	Admissible moves
$s \in S$	Ξ	$\{A \in \wp(S) \mid s \in F(A)\}$
$A \in \wp(S)$	$\forall$	A

Table 7: Unfolding games for  $F: \wp(S) \to \wp(S)$ 

The winning conditions of finite matches are standard (the player that got stuck loses the match). The difference between  $\mathcal{U}^{\mu}(F)$  and  $\mathcal{U}^{\nu}(F)$  shows up in the winning conditions of infinite matches:  $\exists$  wins the infinite matches of  $\mathcal{U}^{\nu}(F)$ , but  $\forall$  those of  $\mathcal{U}^{\mu}(F)$ .

QED

Observe that the positions in a match of the unfolding game alternate between 'state positions' s, where  $\exists$  needs to pick a subset  $A \subseteq S$  such that s belongs to F(A), and 'subset positions' A, of which  $\forall$  has to pick an element.

**Example 3.13** In fact, we have already seen an example of the unfolding game  $\mathcal{U}^{\nu}$  in the *bisimilarity game* of Definition 1.26. Given two Kripke models S and S', consider the map  $F : \wp(S \times S') \to \wp(S \times S)$  given by

 $F(Z) := \{ (s, s') \in S \times S' \mid Z \text{ is a local bisimulation for } s \text{ and } s' \},\$ 

then it is straightforward to verify that  $\mathcal{B}(\mathbb{S}, \mathbb{S}')$  is nothing but the unfolding game  $\mathcal{U}^{\nu}(F)$ .

The following proposition substantiates the slogan that ' $\nu$  means unfolding,  $\mu$  means finite unfolding'.

**Theorem 3.14** Let S be some set and let  $F : \wp(S) \to \wp(S)$  be a monotone operation. Then

- 1. GFP. $F = \{s \in S \mid s \in \operatorname{Win}_\exists (\mathcal{U}^{\nu}(F))\},\$
- 2. LFP. $F = \{s \in S \mid s \in \operatorname{Win}_{\exists}(\mathcal{U}^{\mu}(F))\},\$

**Proof.** For the inclusion  $\supseteq$  of part 1, it suffices to prove that  $W := S \cap \text{Win}_{\exists}(\mathcal{U}^{\nu}(F))$  is a postfixpoint of F:

$$W \subseteq F(W). \tag{25}$$

Let s be an arbitrary point in W, and suppose that  $\exists$ 's winning strategy tells her to choose  $A \subseteq S$  at position s. Then no matter what element  $s_1 \in A$  is picked by  $\forall$ ,  $\exists$  can continue the match and win. Hence, all elements of A are winning positions for  $\exists$ . But from  $A \subseteq W$  it follows that  $F(A) \subseteq F(W)$ , and by the legitimacy of  $\exists$ 's move A at s it holds that  $s \in F(A)$ . We conclude that  $s \in F(W)$ , which proves (25).

For the converse inclusion  $\subseteq$  of part 1 of the proposition, take an arbitrary point  $s \in$  GFP.*F*. We need to provide  $\exists$  with a winning strategy in the unfolding game  $\mathcal{U}^{\nu}(F)$  starting at *s*. This strategy is actually as simple as can be:  $\exists$  should always play GFP.*F*. Since GFP.*F* = *F*(GFP.*F*), this strategy prescribes legitimate moves for  $\exists$  at every point in GFP.*F*. And, if she sticks to this strategy,  $\exists$  will stay alive forever and thus win the match, no matter what  $\forall$ 's responses are.

For the second part of the theorem, let W denote the set  $W := S \cap \operatorname{Win}_{\exists}(\mathcal{U}^{\mu}(F))$  of states in S that are winning positions for  $\exists$  in  $\mathcal{U}^{\mu}(F)$ . We first prove the inclusion  $W \subseteq \operatorname{LFP}.F$ . Clearly it suffices to show that all points outside the set LFP.F are winning positions for  $\forall$ .

Consider a point  $s \notin LFP.F$ . If  $s \notin F(A)$  for any  $A \subseteq S$  then  $\exists$  is stuck, hence loses immediately, and we are done. Otherwise, suppose that  $\exists$  starts a match of  $\mathcal{U}^{\mu}(F)$  by playing some set  $B \subseteq S$  with  $s \in F(B)$ . We claim that B is not a subset of LFP.F, since otherwise we would have  $F(B) \subseteq F(LFP.F) \subseteq LFP.F$ ; which would contradict the fact that  $s \notin LFP.F$ . But if  $B \not\subseteq LFP.F$  then  $\forall$  may continue the match by choosing a point  $s_1 \in B \setminus LFP.F$ . Now  $\forall$  can use the same strategy from  $s_1$  as he used from s, and so on. This strategy guarantees that either  $\exists$  gets stuck after finitely many rounds (in case  $\forall$  manages to pick an  $s_n$  for which there is no A such that  $s_n \in F(A_n)$ , or else the match will last forever. In both cases  $\forall$  wins the match.

For the opposite inclusion  $\subseteq$  of part 2, it suffices to show that W is a prefixpoint of F, that is,  $F(W) \subseteq W$ . For that purpose, let  $s \in S$  be such that  $s \in F(W)$ . In order to show that  $s \in W$  we need to provide  $\exists$  with a winning strategy in  $\mathcal{U}^{\mu}(F)$ , starting at s. But this is straightforward: since  $s \in F(W)$ , the set W itself is a legitimate move for  $\exists$  at position s. Then, after  $\forall$  picks some element  $t \in W$ , she can simply continue with her strategy in  $\mathcal{U}^{\mu}(F)$ that is winning when starting at position t. QED

# 3.3 Vectorial fixpoints

Suppose that we are given a finite family  $\{\mathbb{C}_1, \ldots, \mathbb{C}_n\}$  of complete lattices, and put  $\mathbb{C} = \prod_{1 \leq i \leq n} \mathbb{C}_i$ . Given a finite family of monotone maps  $f_1, \ldots, f_n$  with  $f_i : C \to C_i$ , we may define the map  $f : C \to C$  given by  $f(c) := (f_1(c), \ldots, f_n(c))$ . Monotonicity of f is an easy consequence of the monotonicity of the maps  $f_i$  separately, and so by completeness of  $\mathbb{C}$ , f has a least and a greatest fixpoint. In this context we will also use vector notation, for instance writing

$$\mu \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{pmatrix} \cdot \begin{pmatrix} f_1(x_1, \dots, x_n) \\ f_2(x_1, \dots, x_n) \\ \vdots \\ f_n(x_1, \dots, x_n) \end{pmatrix}$$

for LFP. f. An obvious question is whether one may express these multi-dimensional fixpoints in terms of one-dimensional fixpoints of maps that one may associate with  $f_1, \ldots, f_n$ .

The answer to this question is positive, and the basic observation facilitating the computation of multi-dimensional fixpoints is the following so-called *Bekič principle*.

**Proposition 3.15** Let  $\mathbb{D}_1$  and  $\mathbb{D}_2$  be two complete lattices, and let  $f_i : D_1 \times D_2 \to D_i$  for i = 1, 2 be monotone maps. Then

$$\eta \left(\begin{array}{c} x\\ y \end{array}\right) \cdot \left(\begin{array}{c} f_1(x,y)\\ f_2(x,y) \end{array}\right) = \left(\begin{array}{c} \eta x.f_1(x,\eta y.f_2(x,y))\\ \eta y.f_2(\eta x.f_1(x,y),y) \end{array}\right)$$

where  $\eta$  uniformly denotes either  $\mu$  or  $\nu$ .

**Proof.** Define  $\mathbb{D} := \mathbb{D}_1 \times \mathbb{D}_2$ , and let  $f : D \to D$  be given by putting  $f(d) := (f_1(d), f_2(d))$ . Then f is clearly monotone, and so it has both a least and a greatest fixpoint.

By the order duality principle it suffices to consider the case  $\eta = \mu$  of least fixed points only. Suppose that  $(a_1, a_2)$  is the least fixpoint of f, and let  $b_1$  and  $b_2$  be given by

$$\begin{cases} b_1 := \mu x.f_1(x, \mu y.f_2(x, y)), \\ b_2 := \mu y.f_2(\mu x.f_1(x, y), y). \end{cases}$$

Then we need to show that  $a_1 = b_1$  and  $a_2 = b_2$ .

By definition of  $(a_1, a_2)$  we have

$$\begin{cases} a_1 = f_1(a_1, a_2), \\ a_2 = f_2(a_1, a_2), \end{cases}$$

whence we obtain

$$\begin{cases} \mu x.f_1(x,a_2) \leq a_1 & \text{and} \\ \mu y.f_2(a_1,y) \leq a_2, \end{cases}$$

From this we obtain by monotonicity that

$$f_2(\mu x. f_1(x, a_2), a_2) \le f_2(a_1, a_2) = a_2,$$

so that we find  $b_2 \leq a_2$  by definition of  $b_2$ . Likewise we may show that  $b_1 \leq a_1$ .

Conversely, by definition of  $b_1$  and  $b_2$  we have

$$\left(\begin{array}{c} b_1\\ b_2\end{array}\right) = \left(\begin{array}{c} f_1(b_1,\mu y.f_2(b_1,y))\\ f_2(\mu x.f_1(x,b_2),b_2)\end{array}\right).$$

Then with  $c_2 := \mu y f_2(b_1, y)$ , we have  $b_1 = f_1(b_1, c_2)$ . Also, by definition of  $c_2$  as a fixpoint,  $c_2 = f_2(b_1, c_2)$ . Putting these two identities together, we find that

$$\begin{pmatrix} b_1 \\ c_2 \end{pmatrix} = \begin{pmatrix} f_1(b_1, c_2) \\ f_2(b_1, c_2) \end{pmatrix} = f \begin{pmatrix} b_1 \\ c_2 \end{pmatrix}.$$

Hence by definition of  $(a_1, a_2)$ , we find that  $a_1 \leq b_1$  (and that  $a_2 \leq c_2$ , but that is of less interest now). Analogously, we may show that  $a_2 \leq b_2$ . QED

Proposition 3.15 allows us to compute the least and greatest fixpoints of any monotone map f on a finite product of complete lattices in terms of the least and greatest fixpoints of operations on the factors of the product, through a *elimination method* that is reminiscent of Gaussian elimination in linear algebra.

To see how it works, suppose that we are dealing with lattices  $\mathbb{C}_1, \ldots, \mathbb{C}_{n+1}, \mathbb{C}$  and maps  $f_1, \ldots, f_{n+1}, f$ , just as described above, and that we want to compute  $\eta \vec{x} \cdot f$ , that is, find the elements  $a_1, \ldots, a_{n+1}$  such that

$$\begin{pmatrix} a_1 \\ a_2 \\ \vdots \\ a_{n+1} \end{pmatrix} = \eta \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_{n+1} \end{pmatrix} \cdot \begin{pmatrix} f_1(x_1, \dots, x_n, x_{n+1}) \\ f_2(x_1, \dots, x_n, x_{n+1}) \\ \vdots \\ f_{n+1}(x_1, \dots, x_n, x_{n+1}) \end{pmatrix}$$

We may define

$$g_{n+1}(x_1,\ldots,x_n) := \eta x_{n+1} \cdot f_{n+1}(x_1,\ldots,x_{n+1})$$

and then use Proposition 3.15, with  $\mathbb{D}_1 = \mathbb{C}_1 \times \cdots \times \mathbb{C}_n$ , and  $\mathbb{D}_2 = \mathbb{C}_{n+1}$ , to obtain

$$\begin{pmatrix} a_1 \\ a_2 \\ \vdots \\ a_n \end{pmatrix} = \eta \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{pmatrix} \cdot \begin{pmatrix} f_1(x_1, \dots, x_n, g_{n+1}(x_1, \dots, x_n)) \\ f_2(x_1, \dots, x_n, g_{n+1}(x_1, \dots, x_n)) \\ \vdots \\ f_n(x_1, \dots, x_n, g_{n+1}(x_1, \dots, x_n)) \end{pmatrix}$$

We may then inductively assume to have obtained the tuple  $(a_1, \ldots, a_n)$ . Finally, we may compute  $a_{n+1} := g_{n+1}(a_1, \ldots, a_n)$ .

Observe that in case  $\mathbb{C}_i = \mathbb{C}_j$  for all i, j and the operations  $f_i$  are all term definable in some formal fixpoint language, then each of the components  $a_i$  of the extremal fixpoints of f can also be expressed in this language.

#### 3.4Algebraic semantics for the modal $\mu$ -calculus

# **Basic definitions**

In order to define the algebraic semantics of the modal  $\mu$ -calculus, we need to consider formulas as operations on the power set of the (state space of a) transitions system, and we have to prove that such operations indeed have least and greatest fixpoints. In order to make this precise, we need some preliminary definitions.

**Definition 3.16** Given an LTS  $\mathbb{S} = \langle S, V, R \rangle$  and subset  $X \subseteq S$ , define the valuation  $V[x \mapsto$ X] by putting

$$V[x \mapsto X](y) := \begin{cases} V(y) & \text{if } y \neq x, \\ X & \text{if } y = x. \end{cases}$$

Then, the LTS  $S[x \mapsto X]$  is given as the structure  $\langle S, V[x \mapsto X], R \rangle$ .

Now inductively assume that  $\llbracket \varphi \rrbracket^{\mathbb{S}}$  has been defined for all LTSs. Given a labelled transition system S and a propositional variable  $x \in \mathsf{P}$ , each formula  $\varphi$  induces a map  $\varphi_x^{\mathbb{S}}: \wp(S) \to \wp(S)$  defined by []

$$\varphi_x^{\mathbb{S}}(X) := \llbracket \varphi \rrbracket^{\mathbb{S}[x \mapsto X]}$$

**Example 3.17** a) Where  $\varphi_a = p \lor x$  we have  $(\varphi_a)_x^{\mathbb{S}}(X) = \llbracket p \lor x \rrbracket^{\mathbb{S}[x \mapsto X]} = V(p) \cup X$ . b) Where  $\varphi_b = \overline{x}$  we have  $(\varphi_b)_x^{\mathbb{S}}(X) = \llbracket \overline{x} \rrbracket^{\mathbb{S}[x \mapsto X]} = S \setminus X$ . c) Where  $\varphi_c = p \lor \diamond_d x$  we find  $(\varphi_c)_x^{\mathbb{S}}(X) = \llbracket p \lor \diamond_d x \rrbracket^{\mathbb{S}[x \mapsto X]} = V(p) \cup \langle R_d \rangle X$ . d) Where  $\varphi_d = \diamond_d \overline{x}$  we find  $(\varphi_d)_x^{\mathbb{S}}(X) = \llbracket \diamond_d \overline{x} \rrbracket^{\mathbb{S}[x \mapsto X]} = \langle R_d \rangle (S \setminus X)$ .

**Remark 3.18** Clearly, relative to a model S, X is a fixpoint of  $\varphi_x^{\mathbb{S}}$  iff  $X = \varphi_x^{\mathbb{S}}(X)$ ; a prefixpoint iff  $\varphi_x^{\mathbb{S}}(X) \subseteq X$  and a postfix point iff  $X \subseteq \varphi_x^{\mathbb{S}}(X)$ .

Writing  $\mathbb{S} \Vdash \varphi$  for  $S = \llbracket \varphi \rrbracket^{\mathbb{S}}$ , an alternative but equivalent way of formulating this is to say that in S, X is a prefixpoint of a formula  $\varphi(x)$  iff  $\mathbb{S}[x \mapsto X] \Vdash \varphi \to x$ , a postfixpoint iff  $\mathbb{S}[x \mapsto X] \Vdash x \to \varphi$ , and a fixpoint iff  $\mathbb{S}[x \mapsto X] \Vdash x \leftrightarrow \varphi$ .  $\triangleleft$ 

**Example 3.19** Consider the formulas of Example 3.17.

a) The sets V(p) and S are fixpoints of  $\varphi_a$ , as is in fact any X with  $V(p) \subseteq X \subseteq S$ .

b) Since we do not consider structures with empty domain, the formula  $\overline{x}$  has no fixpoints at all. (Otherwise X would be identical to its own complement relative to some nonempty set S.)

c) Two fixpoints of  $\varphi_c$  were already given in Example 2.1.

d) Consider any model  $\mathbb{Z} = \langle Z, S, V \rangle$  based on the set Z of integers, where  $S = \{(z, z+1) \mid z \in Z \}$  $z \in Z$  is the successor relation. Then the only two fixpoints of  $\varphi_d$  are the sets of even and odd numbers, respectively.  $\triangleleft$ 

In particular, it is not the case that every formula has a least fixpoint. If we can guarantee that the induced function  $\varphi_x^{\mathbb{S}}$  of  $\varphi$  is monotone, however, then the Knaster-Tarski theorem (Theorem 3.4) provides both least and greatest fixpoints of  $\varphi_x^{\mathbb{S}}$ . Precisely for this reason, in the definition of fixpoint formulas, we imposed the condition in the clauses for  $\eta x.\varphi$ , that x may only occur positively in  $\varphi$ . As we will see, this condition on x guarantees monotonicity of the function  $\varphi_x^{\mathbb{S}}$ .

**Definition 3.20** Given a  $\mu$ ML<sub>D</sub>-formula  $\varphi$  and a labelled transition system  $\mathbb{S} = \langle S, V, R \rangle$ , we define the meaning  $[\![\varphi]\!]^{\mathbb{S}}$  of  $\varphi$  in  $\mathbb{S}$ , together with the map  $\varphi_x^{\mathbb{S}} : \wp(S) \to \wp(S)$  by the following simultaneous formula induction:

$$\begin{split} \llbracket \bot \rrbracket^{\mathbb{S}} &= \varnothing & \llbracket \top \rrbracket^{\mathbb{S}} &= S \\ \llbracket p \rrbracket^{\mathbb{S}} &= V(p) & \llbracket \overline{p} \rrbracket^{\mathbb{S}} &= S \setminus V(p) \\ \llbracket \varphi \lor \psi \rrbracket^{\mathbb{S}} &= \llbracket \varphi \rrbracket^{\mathbb{S}} \cup \llbracket \psi \rrbracket^{\mathbb{S}} & \llbracket \varphi \land^{\mathbb{S}} \cup \llbracket \psi \rrbracket^{\mathbb{S}} & \llbracket \varphi \land^{\mathbb{S}} \cap \llbracket \psi \rrbracket^{\mathbb{S}} \\ \llbracket \diamond_{d} \varphi \rrbracket^{\mathbb{S}} &= \langle R_{d} \rangle \llbracket \varphi \rrbracket^{\mathbb{S}} & \llbracket \Box_{d} \varphi \rrbracket^{\mathbb{S}} &= \llbracket R_{d} \rrbracket \llbracket \varphi \rrbracket^{\mathbb{S}} \\ \llbracket \mu x. \varphi \rrbracket^{\mathbb{S}} &= \bigcap \operatorname{PRE}(\varphi_{x}^{\mathbb{S}}) & \llbracket \nu x. \varphi \rrbracket^{\mathbb{S}} &= \bigcup \operatorname{POS}(\varphi_{x}^{\mathbb{S}}) \end{aligned}$$

The map  $\varphi_x^{\mathbb{S}}$ , for  $x \in \mathsf{Prop}$ , is given by  $\varphi_x^{\mathbb{S}}(X) = \llbracket \varphi \rrbracket^{\mathbb{S}[x \mapsto X]}$ .

**Theorem 3.21** Let  $\varphi$  be an  $\mu$ ML<sub>D</sub>-formula, in which x occurs only positively, and let S be a labelled transition system. Then  $\llbracket \mu x. \varphi \rrbracket^{\mathbb{S}} = LFP. \varphi_x^{\mathbb{S}}$ , and  $\llbracket \nu x. \varphi \rrbracket^{\mathbb{S}} = GFP. \varphi_x^{\mathbb{S}}$ .

**Proof.** This is an immediate consequence of the Knaster-Tarski theorem, provided we can prove that  $\varphi_x^{\mathbb{S}}$  is monotone in x if all occurrences of x in  $\varphi$  are positive. We leave the details of this proof to the reader (see Exercise 3.2). QED

#### Negation in the modal $\mu$ -calculus

It follows from the definitions that the set  $\mu ML_{\rm D}$  is closed under taking *negations*. Informally, let  $\sim \varphi$  be the result of simultaneously replacing all occurrences of  $\top$  with  $\perp$ , of p with  $\overline{p}$  and vice versa (for *free* variables p), of  $\wedge$  with  $\vee$ , of  $\Box_d$  with  $\diamond_d$ , of  $\mu x$  with  $\nu x$ , and vice versa, while leaving occurrences of bound variables unchanged. As an example,  $\sim (\mu x.p \lor \Diamond x) = \nu x.\overline{p} \land \Box x.$ Formally, it is easiest to define  $\sim \varphi$  via the *boolean dual* of  $\varphi$ .

**Definition 3.22** Given a modal fixpoint formula  $\varphi$ , we define its *boolean dual*  $\varphi^{\partial}$  inductively as follows:

$\perp^\partial$	:=	Т	$\top^{\partial}$	:=	$\perp$
$p^{\partial}$	:=	p	$(\overline{p})^{\partial}$	:=	$\overline{p}$
$(\varphi \vee \psi)^\partial$	:=	$arphi^\partial\wedge\psi^\partial$	$(\varphi \wedge \psi)^\partial$	:=	$\varphi^\partial \vee \psi^\partial$
$(\diamondsuit_d \varphi)^\partial$	:=	$\Box_d arphi^\partial$	$(\Box_d \varphi)^\partial$	:=	$\diamondsuit_d \varphi^\partial$
$(\mu x. \varphi)^{\partial}$	:=	$ u x. arphi^{\partial}$	$(\nu x. \varphi)^{\partial}$	:=	$\mu x. \varphi^{\partial}$

Based on this definition, we define the formula  $\sim \varphi$  as the formula  $\varphi^{\partial}[p \rightleftharpoons \overline{p} \mid p \in FV(\varphi)]$ that we obtain from  $\varphi^{\partial}$  by replacing all occurrences of p with  $\overline{p}$ , and vice versa, for all free proposition letters  $p \in FV(\varphi)$ . <1

**Example 3.23** Here are two examples:

Note the difference between  $\sim \varphi$  and  $\sim \psi$  with respective to the propositional variable p, which is free in  $\varphi$  but bound in  $\psi$ .  $\triangleleft$ 

 $\triangleleft$ 

The following proposition states that the operation  $\sim$  functions as a standard boolean negation. We let  $\sim_S X := S \setminus X$  denote the complement of X in S.

**Proposition 3.24** Let  $\varphi$  be a modal fixpoint formula. Then  $\sim \varphi$  corresponds to the negation of  $\varphi$ , that is,

$$\llbracket \sim \varphi \rrbracket^{\mathbb{S}} = \sim_{S} \llbracket \varphi \rrbracket^{\mathbb{S}}$$
(26)

for every labelled transition system S.

**Proof.** We first show, by induction on  $\varphi$ , that  $\varphi^{\partial}$  corresponds to the boolean dual of  $\varphi$ . For this purpose, given a labelled transition system  $\mathbb{S} = (S, R, V)$ , we let  $\mathbb{S}^{\sim}$  denote the *complemented* model, that is, the structure  $(S, R, V^{\sim})$ , where  $V^{\sim}(p) := \sim_S V(p)$ . Then we claim that

$$\llbracket \varphi^{\partial} \rrbracket^{\mathbb{S}} = \sim_{S} \llbracket \varphi \rrbracket^{\mathbb{S}^{\sim}}, \tag{27}$$

and we prove this statement by induction on the complexity of  $\varphi$ . Leaving all other cases as exercises for the reader, we concentrate on the inductive case where  $\varphi$  is of the form  $\mu x.\psi$ . In this case the left hand side of (27) evaluates to

$$\llbracket (\mu x.\psi)^{\partial} \rrbracket^{\mathbb{S}} = \llbracket \nu x.\psi^{\partial} \rrbracket^{\mathbb{S}}$$
 (Definition  $(\mu x.\psi)^{\partial}$ )  
= GFP. $(\psi^{\partial})_x^{\mathbb{S}}$  (Theorem 3.21)

while for the right hand side we find

$$\sim_{S} \llbracket \mu x. \psi \rrbracket^{\mathbb{S}^{\sim}} = \sim_{S} \text{LFP.} \psi_{x}^{\mathbb{S}^{\sim}}$$
(Theorem 3.21)  
= GFP. $(\psi_{x}^{\mathbb{S}^{\sim}})^{\partial}$  (Proposition 3.11)

In other words, to prove (27) it suffices to show that

$$(\psi^{\partial})_x^{\mathbb{S}} = (\psi_x^{\mathbb{S}^{\sim}})^{\partial}.$$
 (28)

To this aim, take an arbitrary subset U of S. Applying the map on the left hand side of (28) to U, we find

$$(\psi^{\partial})_x^{\mathbb{S}}(U) = \llbracket \psi^{\partial} \rrbracket^{\mathbb{S}[x \mapsto U]}$$

while the map on the right hand side yields

$$(\psi_x^{\mathbb{S}^{\sim}})^{\partial}(U) = \sim_S \psi_x^{\mathbb{S}^{\sim}}(\sim_S U) = \sim_S \llbracket \psi \rrbracket^{(\mathbb{S}^{\sim}[x \mapsto \sim_S U])} = \sim_S \llbracket \psi \rrbracket^{(\mathbb{S}[x \mapsto U])^{\sim}},$$

so that by the inductive hypothesis we find that  $(\psi^{\partial})_x^{\mathbb{S}}(U) = (\psi_x^{\mathbb{S}^{\sim}})^{\partial}(U)$ , as required to prove (28), and thus (27).

In other words, we have shown that the formula  $\varphi^{\partial}$  indeed behaves as the boolean dual of  $\varphi$ . To see that, likewise, the formula  $\sim \varphi$  behaves as the negation of  $\varphi$ , we now show how to derive (26) from (27). First observe that for any formula  $\chi$  we have

$$\llbracket \chi[p \rightleftharpoons \overline{p} \mid p \in FV(\chi)] \rrbracket^{\mathbb{S}} = \llbracket \chi \rrbracket^{\mathbb{S}^{\sim}}.$$
(29)

But then, taking  $\varphi^{\partial}$  for  $\chi$ , we find that

$$\llbracket \sim \varphi \rrbracket^{\mathbb{S}} = \llbracket \varphi^{\partial} [p \rightleftharpoons \overline{p} \mid p \in FV(\varphi)] \rrbracket^{\mathbb{S}} = \llbracket \varphi^{\partial} \rrbracket^{\mathbb{S}^{\sim}} = \sim_{S} \llbracket \varphi \rrbracket^{(\mathbb{S}^{\sim})^{\sim}} = \sim_{S} \llbracket \varphi \rrbracket^{\mathbb{S}},$$

where the first equality holds by the definition of  $\sim \varphi$ , the second by (29), the third equality is (27), and the fourth equality follows from the trivial observation that  $(\mathbb{S}^{\sim})^{\sim} = \mathbb{S}$ . QED Lectures on the modal  $\mu$ -calculus

**Remark 3.25** It follows from the Proposition above that we could indeed have based the language of the modal  $\mu$ -calculus on a smaller alphabet of primitive symbols. Given a set D of atomic actions, we could have defined the set of modal fixpoint formulas using the following induction:

 $\varphi ::= \bot \mid p \mid \neg \varphi \mid \varphi \lor \varphi \mid \diamond_d \varphi \mid \mu x.\varphi$ 

where p and x are propositional variables,  $d \in D$ , and in  $\mu x.\varphi$ , all free occurrences of x must be positive (that is, under an even number of negation symbols). Here we define  $FV(\neg \varphi) = FV(\varphi)$  and  $BV(\neg \varphi) = BV(\varphi)$ .

In this set-up, the constant  $\top$  and the connectives  $\land$  and  $\Box_d$  are defined using the standard abbreviations, while for the greatest fixpoint operator we may put

$$\nu x.\varphi := \neg \mu x. \neg \varphi(\neg x).$$

Note the *triple* use of the negation symbol here, which can be explained by Proposition 3.11 and the observation that we may think of  $\neg \varphi(\neg x)$  as the formulas  $\varphi^{\partial}$ .

# Other immediate consequences

Earlier on we defined the notions of *clean* and *guarded* formulas.

**Proposition 3.26** Every fixpoint formula is equivalent to a clean formula, and hence, to a tidy one.

**Proof.** We leave this proof as an exercise for the reader. QED

**Proposition 3.27** Every fixpoint formula is equivalent to a guarded formula.

**Proof.** (Sketch) We prove this proposition by formula induction. Clearly the only nontrivial case to consider concerns the fixpoint operators. Consider a formula of the form  $\eta x.\delta(x)$ , where  $\delta(x)$  is guarded and clean, and suppose that x has an unguarded occurrence in  $\delta$ .

First consider an unguarded occurrence of x in  $\delta(x)$  inside a fixpoint subformula, say, of the form  $\theta y.\gamma(x,y)$ . By induction hypothesis, all occurrences of y in  $\gamma(x,y)$  are guarded. Obtain the formula  $\overline{\delta}$  from  $\delta$  by replacing the subformula  $\theta y.\gamma(x,y)$  with  $\gamma(x,\theta y.\gamma(x,y))$ . Then clearly  $\overline{\delta}$  is equivalent to  $\delta$ , and all of the unguarded occurrences of x in  $\overline{\delta}$  are outside of the scope of the fixpoint operator  $\theta$ .

Continuing like this we obtain a formula  $\eta x.\delta(x)$  which is equivalent to  $\eta x.\delta(x)$ , and in which none of the unguarded occurrences of x lies inside the scope of a fixpoint operator. That leaves  $\wedge$  and  $\vee$  as the only operation symbols in the scope of which we may find unguarded occurrences of x.

From now on we only consider the case where  $\eta = \mu$ , leaving the very similar case where  $\eta = \nu$  as an exercise. Clearly, using the laws of classical propositional logic, we may bring the formula  $\overline{\delta}$  into conjunctive normal form

$$(x \lor \alpha_1(x)) \land \dots \land (x \lor \alpha_n(x)) \land \beta(x), \tag{30}$$

where all occurrences of x in  $\alpha_1, \ldots, \alpha_n$  and  $\beta$  are guarded. (Note that we may have  $\beta = \top$ , or  $\alpha_i = \bot$  for some *i*.)

Clearly (30) is equivalent to the formula

$$\delta'(x) := (x \lor \alpha(x)) \land \beta(x),$$

where  $\alpha = \alpha_1 \wedge \cdots \wedge \alpha_n$ . Thus we are done if we can show that

$$\mu x.\delta'(x) \equiv \mu x.\alpha(x) \wedge \beta(x). \tag{31}$$

Since  $\alpha \wedge \beta$  implies  $\delta'$ , it is easy to see (and left for the reader to prove) that  $\mu x.\alpha \wedge \beta$  implies  $\mu x.\delta'$ . For the converse, it suffices to show that  $\varphi := \mu x.\alpha(x) \wedge \beta(x)$  is a prefixpoint of  $\delta'(x)$ . But it is not hard to derive from  $\varphi \equiv \alpha(\varphi) \wedge \beta(\varphi)$  that

$$\delta'(\varphi) = (\varphi \lor \alpha(\varphi)) \land \beta(\varphi) \equiv ((\alpha(\varphi) \land \beta(\varphi)) \lor \alpha(\varphi)) \land \beta(\varphi) \equiv \alpha(\varphi) \land \beta(\varphi) \equiv \varphi,$$

which shows that  $\varphi$  is in fact a fixpoint, and hence certainly a prefixpoint, of  $\delta'(x)$ . QED

Combining the proofs of the previous two propositions one easily shows the following.

**Proposition 3.28** Every fixpoint formula is equivalent to a clean, guarded formula, and hence, to a tidy, guarded one.

**Remark 3.29** The equivalences of the above propositions are in fact *effective* in the sense that there are algorithms for computing an equivalent clean and/or guarded equivalent to an arbitrary formula in  $\mu$ ML. It is an interesting question what the complexity of these algorithms is, and what the minimum *size* of the equivalent formulas is. We will return to this issue later on, but already mention here that there are formulas that are exponentially smaller than any of their clean equivalents. The analogous question for guarded transformations, i.e., constructions that provide guarded equivalents to an arbitrary formula, is open.

# 3.5 Adequacy

In this section we prove the *equivalence* of the two semantic approaches towards the modal  $\mu$ calculus. Since the algebraic semantics is usually taken to be the more fundamental notion, we refer to this result as the *Adequacy Theorem* stating, informally, that games are an adequate way of working with the algebraic semantics.

We first consider the subformula game.

**Theorem 3.30 (Adequacy of the subformula game)** Let  $\xi$  be a clean  $\mu$ ML<sub>D</sub>-formula. Then for all labelled transition systems S and all states s in S:

$$s \in \llbracket \xi \rrbracket^{\mathbb{S}} \iff (\xi, s) \in \operatorname{Win}_{\exists}(\mathcal{E}(\xi, \mathbb{S})).$$
(32)

**Proof.** The theorem is proved by induction on the complexity of  $\xi$ . We only discuss the inductive steps where  $\xi$  is of the form  $\eta x.\delta$  (with  $\eta$  denoting either  $\mu$  or  $\nu$ ), leaving the other cases as exercises to the reader.

**Preparatory observations** Our proof for these inductive cases will involve *three* games: the unfolding game for  $\delta_x^{\mathbb{S}}$ , and the evaluation games for  $\xi$  and  $\delta$ , respectively. It is based on two key observations: One concerns the nature of the unfolding game for  $\delta_x^{\mathbb{S}}$  and its role in the semantics for  $\eta x.\delta$ ; the other observation concerns the similarity between the evaluation games for  $\xi$  and for  $\delta$ .

1. Starting with the first observation, note that by definition of the algebraic semantics of the fixpoint operators, the set  $[\eta x.\delta]^{\mathbb{S}}$  is the least/greatest fixed point of the map  $\delta_x^{\mathbb{S}} : \wp(S) \to \wp(S)$ , and that by our earlier Theorem 3.14 on unfolding games, we have

$$\llbracket \eta x.\delta \rrbracket^{\mathbb{S}} = \operatorname{Win}_{\exists} (\mathcal{U}^{\eta}(\delta_x^{\mathbb{S}})) \cap S.$$
(33)

Hence, in order to prove (32), it suffices to show that, for any state  $s_0$ :

$$s_0 \in \operatorname{Win}_{\exists}(\mathcal{U}^{\eta}(\delta_x^{\mathbb{S}})) \iff (\xi, s_0) \in \operatorname{Win}_{\exists}(\mathcal{E}(\xi, \mathbb{S})).$$
 (34)

In other words, the crucial tasks in the proof of this inductive step concern the transformation of a winning strategy for  $\exists$  in the unfolding game  $\mathcal{U}^{\eta}(\delta_x^{\mathbb{S}})@s_0$  to a winning strategy for her in the evaluation game  $\mathcal{E}(\xi, \mathbb{S})@(\xi, s_0)$ , and vice versa.

Given the importance of the unfolding game for  $\delta_x^{\mathbb{S}}$  then, let us look at it in a bit more detail. Note that a round of this game, starting at position  $s \in S$ , consists of  $\exists$  picking a subset  $A \subseteq S$  that is subject to the constraint that  $s \in \delta_x^{\mathbb{S}}(A) = \llbracket \delta \rrbracket^{\mathbb{S}[x \mapsto A]}$ . But here the inductive hypothesis comes into play: it implies that, for all  $A \subseteq S$ , we have

$$s \in \delta_x^{\mathbb{S}}(A) \iff (\delta, s) \in \operatorname{Win}_{\exists}(\mathcal{E}(\delta, \mathbb{S}[x \mapsto A])).$$
 (35)

In other words, each round of the unfolding game for the map  $\delta_x^{\mathbb{S}}$  crucially involves the evaluation game for the formula  $\delta$ , played on some x-variant  $\mathbb{S}[x \mapsto A]$  of  $\mathbb{S}$ .

2. This leads us to the comparison between the games  $\mathcal{G} := \mathcal{E}(\xi, \mathbb{S})$  and  $\mathcal{G}_A := \mathcal{E}(\delta, \mathbb{S}[x \mapsto A])$ . The second key observation in the inductive step for the fixpoint operators is that these games are *very* similar indeed. For a start, the positions of the two games are essentially the same. Positions of the form  $(\xi, t)$ , which exist in the first game but not in the second, are the only exception — but in  $\mathcal{G}$ , any position  $(\xi, t)$  is immediately and automatically succeeded by the position  $(\delta, t)$  which does exist in the second game. What is important is that the positions for  $\exists$  are exactly the same in the two games, and thus we may apply her positional strategies for the one game in the other game as well. The only real difference between the games shows up in the rule concerning positions of the form (x, u). In  $\mathcal{G}_A$ , x is a *free* variable  $(x \in FV(\delta))$ , so in a position (x, u) the game is over, the winner being determined by u being a member of A or not. In  $\mathcal{G}$  however, x is *bound*, so in position (x, u), the variable x will get unfolded to  $\delta$ .

Combining these two observations, the key insight in the proof of (34) will be to think of  $\mathcal{E}(\xi, \mathbb{S})$  as a variant of the unfolding game  $\mathcal{U} := \mathcal{U}^{\eta}(\delta_x^{\mathbb{S}})$  where each round of  $\mathcal{U}$  corresponds to a version of the game  $\mathcal{G}_T$ , with T being the subset of S picked by  $\exists$  in  $\mathcal{U}$ . We are now ready for the details of the proof of (34).

For the direction from left to right of (34), suppose that  $\exists$  has a winning strategy in the game  $\mathcal{U}$  starting at some position  $s_0$ . Without loss of generality (see Exercise 3.7) we may assume that this strategy is *positional*. Thus we may represent it as a map  $T : S \to \wp(S)$ , where we will write  $T_s$  rather than T(s). By the legitimacy of this strategy, for every  $s \in \operatorname{Win}_{\exists}(\mathcal{U})$  it holds that  $s \in \delta_x^{\mathbb{S}}(T_s)$ . So by the inductive hypothesis (35), for each such swe may assume the existence of a winning strategy  $f_s$  for  $\exists$  in the game  $\mathcal{G}_{T_s}(\emptyset(\delta, s))$ . Given the similarities between the games  $\mathcal{G}$  and  $\mathcal{G}_{T_s}$  (see the discussion above), this strategy is also applicable in the game  $\mathcal{G}(\delta, s)$ , at least, until a new position of the form (x, t) is reached. This suggests the following strategy q for  $\exists$  in  $\mathcal{G}(\emptyset(\xi, s_0))$ :

- 1. after the initial automatic move, the position of the match is  $(\delta, s_0)$ ;  $\exists$  first plays her strategy  $f_{s_0}$ ;
- 2. each time a position (x, s) is reached, the match automatically moves to position  $(\delta, s)$ , where we distinguish cases:
  - (a) if  $s \in Win_{\exists}(\mathcal{U})$  then  $\exists$  continues with  $f_s$ ;
  - (b) if  $s \notin \operatorname{Win}_{\exists}(\mathcal{U})$  then  $\exists$  continues with a random strategy.

First we show that this strategy guarantees that whenever a position of the form (x, s) is visited, s belongs to  $\operatorname{Win}_{\exists}(\mathcal{U})$ , so that case (b) mentioned above never occurs. The proof is by induction on the number of positions (x, s) that have been visited already. For the inductive step, if s is a winning position for  $\exists$  in  $\mathcal{U}$ , then, as we saw,  $f_s$  is a winning strategy for  $\exists$  in the game  $\mathcal{G}_{T_s}@(\delta, s)$ . This means that if a position of the form (x, t) is reached, the variable x must be *true* at t in the model  $\mathbb{S}[x \mapsto T_s]$ , and so t must belong to the set  $T_s$ . But by assumption of the map  $T : S \to \wp(S)$  being a winning strategy in  $\mathcal{U}$ , any element of  $T_s$  is again a member of Win<sub>\exists</sub>( $\mathcal{U}$ ).

In fact we have shown that every unfolding of the variable x in  $\mathcal{G}$  marks a new round in the unfolding game  $\mathcal{U}$ . To see why the strategy g guarantees a win for  $\exists$  in  $\mathcal{G}@(\xi, s_0)$ , consider an arbitrary  $\mathcal{G}@(\xi, s_0)$ -match  $\pi$  in which  $\exists$  plays g. Distinguish cases.

First suppose that x is unfolded only finitely often. Let (x, s) be the last basic position in  $\pi$  where this happens. Given the similarities between the games  $\mathcal{G}$  and  $\mathcal{G}_{T_s}$ , the match from this moment on can be seen as both a g-guided  $\mathcal{G}$ -match and an  $f_s$ -guided  $\mathcal{G}_{T_s}$ -match. As we saw,  $f_s$  is a winning strategy for  $\exists$  in the game  $\mathcal{G}_{T_s}@(\delta, s)$ . But since no further position of the form (x, t) is reached, and  $\mathcal{G}$  and  $\mathcal{G}_{T_s}$  only differ when it comes to x, this means that  $\pi$  is also a win for  $\exists$  in  $\mathcal{G}$ .

If x is unfolded infinitely often during the match  $\pi$ , then by the fact that  $\xi = \eta x.\delta$ , it is the *highest* variable that is unfolded infinitely often. We have to distinguish the case where  $\eta = \nu$  from that where  $\eta = \mu$ . In the first case,  $\exists$  is the winner of the match  $\pi$ , and we are done. If  $\eta = \mu$ , however, x is a least fixpoint variable, and so  $\exists$  would lose the match  $\pi$ . We therefore have to show that this situation cannot occur. Suppose for contradiction that  $s_1, s_2, \ldots$  are the positions where x is unfolded. Then it is easy to verify that the sequence  $s_0 T_{s_0} s_1 T_{s_1} \ldots$  constitutes a  $\mathcal{U}$ -match in which  $\exists$  plays her strategy T. But this is not possible, since T was assumed to be a *winning* strategy for  $\exists$  in the *least* fixpoint game  $\mathcal{U} = \mathcal{U}^{\mu}(\delta_x^{\mathbb{S}})$ . For the direction from right to left of (34), we will show how each positional winning strategies f for  $\exists$  in  $\mathcal{G}$  induces a positional strategy for her in  $\mathcal{U}$ , and that this strategy  $U_f$  is winning for her starting at every position  $s \in W := \{s \in S \mid (\xi, s) \in \text{Win}_{\exists}(\mathcal{G})\}.$ 

So fix a positional winning strategy f for  $\exists$  in  $\mathcal{G}$ ; that is,  $\exists$  is guaranteed to win any f-guided match starting at a position  $(\varphi, t) \in \text{Win}_{\exists}(\mathcal{G})$ . Observe that, as discussed above, we may and will treat f as a positional strategy in each of the games  $\mathcal{G}_A$  as well.

Given a state  $s \in W$ , we let  $\mathbb{T}_f(s)$  be the strategy tree induced by f in  $\mathcal{G}_A@(\delta, s)$ , where A is some arbitrary subset of S. That is, the nodes of  $\mathbb{T}_f$  consist of all f-guided finite matches in  $\mathcal{G}_A$  that start at  $(\delta, s)$ . In more detail, the root of this tree is the single-position match  $(\delta, s)$ ; to define the successor relation of  $\mathbb{T}_f$ , let  $\pi$  be an arbitrary f-guided match starting at position first $(\pi) = (\delta, s)$ . If  $\mathsf{last}(\pi)$  is a position owned by  $\exists$ , then  $\pi$  will have a single successor in  $\mathbb{T}_f$ , viz., the unique extension of  $\pi$  with the position  $f(\pi)$  picked by f. On the other hand, if  $\mathsf{last}(\pi)$  is owned by  $\forall$ , then every possible continuation  $\pi \cdot b$ , where b is an admissible position picked by  $\forall$ , is a successor of  $\pi$ .

We let  $U_f(s)$  be the set of states u such that the position (x, u) occurs as the last element  $(x, u) = \mathsf{last}(\pi)$  of some match  $\pi$  in  $\mathbb{T}_f(s)$ . Any  $\mathcal{G}_A$ -match  $\pi$  ending in a position of the form (x, u) is finished immediately, and thus provides a *leaf* of the tree  $\mathbb{T}_f$ . It is also an easy consequence of the definitions that, whenever  $t \in U_f(s)$  for some  $s \in W$ , then there is an f-guided match  $\pi_{s,t}$  such that  $\mathsf{first}(\pi_{s,t}) = (\delta, s)$  and  $\mathsf{last}(\pi_{s,t}) = (x, t)$ . Note that this match  $\pi_{s,t}$  can be seen both as a (full)  $\mathcal{G}_A$ -match and as a (partial)  $\mathcal{G}$ -match.

Given our definition of a set  $U_f(s) \subseteq S$  for every  $s \in W$ , in effect we have defined a map

$$U_f: W \to \wp(S).$$

CLAIM 1 Viewing this map  $U_f$  as a positional strategy for  $\exists$  in  $\mathcal{U}$ , we claim that in fact it is a *winning* strategy for her in  $\mathcal{U}@s_0$ .

**PROOF OF CLAIM** We need two auxiliary claims on  $U_f$ . First we observe that

if 
$$s \in W$$
 then  $s \in \delta_x^{\mathbb{S}}(U_f(s))$ . (36)

For a proof of (36), it is obvious from the definition of  $U_f(s)$  that f is a positional winning strategy for  $\exists$  in  $\mathcal{G}_{U_f(s)} = \mathcal{E}(\delta, \mathbb{S}[x \mapsto U_f(s)])$  starting at  $(\delta, s)$ . But then by the inductive hypothesis on  $\delta$  we obtain that  $\mathbb{S}[x \mapsto U_f(s)], s \Vdash \delta$ , or, equivalently,  $s \in \delta_x^{\mathbb{S}}(U_f(s))$ .

Second, we claim that

if 
$$s \in W$$
 then  $U_f(s) \subseteq W$ . (37)

To see this, first note that if  $s \in W$  then by definition  $(\xi, s) \in \operatorname{Win}_{\exists}(\mathcal{G})$ ; but from this it is immediate that  $(\delta, s) \in \operatorname{Win}_{\exists}(\mathcal{G})$ , and since we assumed f to be a positional winning strategy for  $\exists$  in  $\mathcal{G}$ , it follows by definition of  $U_f(s)$  that for every  $u \in U_f(s)$  the position (x, u) is winning for  $\exists$  in  $\operatorname{Win}_{\exists}(\mathcal{G})$ . But from this it is easy to derive that both  $(\delta, u)$  and  $(\xi, u)$  are winning position for  $\exists$  in  $\mathcal{G}$  as well. The latter fact then shows that  $u \in W$  and since u was an arbitrary element of  $U_f(s)$ , (37) follows.

We can now prove that  $U_f$  is a winning strategy for  $\exists$  in  $\mathcal{U}@s_0$ . First of all, it follows from (36) that  $U_f(s)$  is a legitimate move in  $\mathcal{U}$  for every position  $s \in W$ . From this and (37) we may conclude that  $\exists$  never gets stuck in an  $U_f$ -guided  $\mathcal{U}$ -match starting at  $s_0$ ; that is, she wins every finite  $U_f$ -guided  $\mathcal{U}$ -match. In case  $\eta = \nu$  this suffices, since in  $UG^{\nu}(\delta_x^{\mathbb{S}})$  all infinite matches are won by  $\exists$ .

Where  $\eta = \mu$  we have a bit more work to do, since in this case all infinite matches of  $\mathcal{U}^{\mu}(\delta_x^{\mathbb{S}})$  are won by  $\forall$ . Suppose for contradiction that  $\pi = s_0 U_f(s_0) s_1 U_f(s_1) \cdots$  would be an infinite  $U_f$ -guided match of  $\mathcal{U}^{\mu}(\delta_x^{\mathbb{S}})$ . Then for every  $i \in \omega$  we have that  $s_{i+1} \in U_f(s_i)$ , so that there is a partial f-guided match  $\pi_i = \pi_{s_i s_{i+1}}$  with first $(\pi_i) = (\delta, s_i)$  and last $(\pi_i) = (x, s_{i+1})$ . But then it is straightforward to verify that the infinite match  $\pi_{\mathcal{G}} := \pi_0 \cdot \pi_1 \cdot \pi_2 \cdots$  we obtain by concatenating the individual f-guided matches  $\pi_i$ , constitutes an infinite f-guided  $\mathcal{G}$ -match with first $(\pi_{\mathcal{G}}) = \text{first}(\pi_0) = (\xi, s_0)$ . Since the highest fixpoint variable unfolded infinitely often during  $\pi_{\mathcal{G}}$  obviously would be x, this match would be lost by  $\exists$ . Here we arrive at the desired contradiction, since  $(\xi, s_0) \in \text{Win}_{\exists}(\mathcal{G})$ , and f was assumed to be a positional winning strategy in  $\mathcal{G}$ .

QED

**Convention 3.31** In the sequel we will use the Adequacy Theorem without further notice. Also, we will write  $\mathbb{S}, s \Vdash \varphi$  in case  $s \in \llbracket \varphi \rrbracket^{\mathbb{S}}$ , or, equivalently,  $\mathbb{S}, s \Vdash_q \varphi$ .

▶ Adequacy of the closure game to be discussed and proved.

**Theorem 3.32 (Adequacy of the closure game)** Let  $\xi$  be a tidy  $\mu$ ML<sub>D</sub>-formula. Then for all labelled transition systems S and all states s in S:

$$s \in \llbracket \xi \rrbracket^{\mathbb{S}} \iff (\xi, s) \in \operatorname{Win}_{\exists}(\mathcal{E}^{c}(\xi, \mathbb{S})).$$
 (38)

### Proof.

▶ ...

By induction on the length of formulas, we will show that every tidy formula  $\varphi$  has the following property:

all formulas 
$$\xi \in Cl(\varphi)$$
 satisfy (32). (39)

We only consider the case where  $\varphi$  is a fixpoint formula, say, it of the form  $\varphi = \eta x \psi$ . Note that the formula  $\psi$  may not be tidy, but we can work with a formula  $\psi' := \psi[x'/x]$ , where x' is a fresh variable. This formula *is* tidy, and shorter than  $\varphi$ , so that the inductive hypothesis applies to it.

We now distinguish cases. If  $\varphi$  is a derivative of  $\psi'$  then we have  $Cl(\varphi) \subseteq Cl(\psi')$  so that (??) is immediate by the inductive hypothesis on  $\psi'$ .

▶ In the sequel we will therefor assume that  $\varphi \notin Cl(\psi')$ .

QED

## Notes

What we now call the Knaster-Tarski Theorem (Theorem 3.4) was first proved by Knaster [9] in the context of power set algebras, and subsequently generalized by Tarski [21] to the setting of complete lattices. The Bekič principle (Proposition 3.15) stems from an unpublished technical report.

#### ▶ more notes and references to be supplied

As far as we know, the results in section 3.2 on the duality between the least and the greatest fixpoint of a monotone map on a complete boolean algebra, are folklore. The characterization of least and greatest fixpoints in game-theoretic terms is fairly standard in the theory of (co-)inductive definitions, see for instance Aczel [1]. The equivalence of the algebraic and the game-theoretic semantics of the modal  $\mu$ -calculus (here formulated as the Adequacy Theorem ??) was first established by Emerson & Jutla [6].

## Exercises

**Exercise 3.1** Prove Proposition 3.6: show that monotone maps on complete lattices are inductive.

Exercise 3.2 Prove Theorem 3.21.

(Hint: given complete lattices  $\mathbb{C}$  and  $\mathbb{D}$ , and a monotone map  $f: C \times D \to C$ , show that the map  $q: D \to C$  given by

$$g(d) := \mu x.f(x,d)$$

is monotone. Here  $\mu x.f(x,d)$  is the least fixpoint of the map  $f_d: C \to C$  given by  $f_d(c) = f(c,d)$ .)

**Exercise 3.3** Let  $F : \wp(S) \to \wp(S)$  be some monotone map. A collection  $\mathcal{D} \in \wp\wp(S)$  of subsets of S is *directed* if for every two sets  $D_0, D_1 \in \mathcal{D}$ , there is a set  $D \in \mathcal{D}$  with  $D_i \subseteq D$  for i = 0, 1. Call F (Scott) continuous if it preserves directed unions, that is, if  $F(\bigcup \mathcal{D}) = \bigcup_{D \in \mathcal{D}} F(D)$  for every directed  $\mathcal{D}$ . Prove the following:

-----

- (a) F is Scott continuous iff for all  $X \subseteq S$ :  $F(X) = \bigcup \{F(Y) \mid Y \subseteq_{\omega} X\}$ . (Here  $Y \subseteq_{\omega} X$  means that Y is a finite subset of X.)
- (b) If F is Scott continuous then the unfolding ordinal of F is at most  $\omega$ .
- (c) Give an example of a Kripke frame  $\mathbb{S} = \langle S, R \rangle$  such that the operation [R] is not continuous.
- (d) Give an example of a Kripke frame  $S = \langle S, R \rangle$  such that the operation [R] has closing/unfolding ordinal  $\omega + 1$ .

**Exercise 3.4** By a mutual induction we define, for every finite set P of propositional variables, the fragment  $\mu ML_{P}^{C}$  by the following grammar:

$$\varphi ::= p \mid \psi \mid \varphi \lor \varphi \mid \varphi \land \varphi \mid \Diamond \varphi \mid \mu q. \varphi',$$

where  $p \in \mathsf{P}, \psi \in \mu \mathsf{ML}$  is a P-free formula, and  $\varphi' \in \mu \mathsf{ML}_{\mathsf{P} \cup \{q\}}^C$ .

Prove that for every Kripke model S, every formula  $\varphi \in \mu \mathbb{ML}_{\mathsf{P}}^{C}$ , and every proposition letter  $p \in \mathsf{P}$ , the map  $\varphi_{p}^{\mathbb{S}} : \wp(S) \to \wp(S)$  is continuous.

**Exercise 3.5** Let  $F : \wp(S) \to \wp(S)$  be a monotone operation, and let  $\gamma_F$  be its unfolding ordinal. Sharpen Corollary 3.7 by proving that the cardinality of  $\gamma_F$  is bounded by |S| (rather than by  $|\wp(S)|$ ).

**Exercise 3.6** The proof of Theorem 3.14 is based on the characterisation of least fixed points as the intersection of all prefixpoints, and similarly, of greatest fixpoints as the union of all postfixpoints. Can you also prove the theorem using the characterisation of least- and greatest fixpoints via ordinal approximations?

**Exercise 3.7** Prove that the unfolding game of Definition 3.12 satisfies positional determinacy. That is, let  $\mathcal{U}^{\mu}(F)$  be the least fixpoint unfolding game for some monotone map  $F : \wp(S) \to \wp(S)$ . Prove the existence of two positional strategies  $f_{\exists} : S \to \wp(S)$  and  $f_{\forall} : \wp(S) \to S$  such that for every position p of the game, either  $f_{\exists}$  is a winning strategy for  $\exists$  in  $\mathcal{U}^{\mu}(F)@p$ , or else  $f_{\forall}$  is a winning strategy for  $\forall$  in  $\mathcal{U}^{\mu}(F)@p$ .

**Exercise 3.8** Let  $\mathbb{C}$  be a complete boolean algebra and let  $f : C \to C$  be a monotone map. Pick an element  $d \in C$  and let  $\mu x.f(x)$  be the least fixpoint of f.

- (a) Show that  $d \wedge \mu x.f(x) = \bot$  iff  $d \wedge \mu x.f(x \wedge \neg d) = \bot$ , where  $\mu x.f(x \wedge \neg d)$  denotes the smallest fixpoint of the map sending any element  $x \in C$  to  $f(x \wedge \neg d)$ .
- (b) Conclude that, for any formula of the form  $\mu x.\varphi$  and an arbitrary formula  $\gamma$ : the formula  $\gamma \wedge \mu x.\varphi$  is satisfiable iff the formula  $\gamma \wedge \mu x.\varphi[x \wedge \neg \gamma/x]$  is satisfiable. (A formula  $\varphi$  is called satisfiable if there exists a pointed Kripke model such that  $\mathbb{S}, s \Vdash \varphi$ .)
  - ▶ add exercise on the closure ordinal of a formula
  - ▶ add exercise on (complete) additivity

# 4 Stream automata and logics for linear time

As we already mentioned in the introduction in the theory of the modal  $\mu$ -calculus and other fixpoint logics a fundamental role is played by automata. As we will see further on, these devices provide a very natural generalization to the notion of a formula. This chapter gives an introduction to the theory of automata operating on (potentially infinite) objects. Whereas in later chapters we will meet various kinds of automata for classifying trees and general transition systems, here we confine our attention to the devices that operate on *streams* or infinite words, these being the simplest nontrivial examples of infinite behavior.

**Convention 4.1** Throughout this chapter (and the next), we will be dealing with some finite alphabet C. Generic elements of C may be denoted as  $c, d, c_0, c_1, \ldots$ , but often it will be convenient to think of C as a set of *colors*. In this case we will denote the elements of C with lower case roman letters that are mnemonic of the most familiar corresponding color ('b' for *blue*, 'g' for green, etcetera).

**Definition 4.2** Given an alphabet C, a C-stream is just an infinite C-sequence, that is, a map  $\gamma : \omega \to C$  from the natural numbers to C (see Appendix A). C-streams will also be called *infinite words* or  $\omega$ -words over C. Sets of C-streams are called *stream languages* or  $\omega$ -languages over C.

**Remark 4.3** This definition is consistent with the terminology we introduced in Chapter 1. There we defined a  $\wp(\mathsf{P})$ -stream or stream model for  $\mathsf{P}$  to be a Kripke model of the form  $\mathbb{S} = \langle \omega, V, Succ \rangle$ , where Succ is the standard successor relation on the set  $\omega$  of natural numbers, and  $V : \mathsf{P} \to \wp(\omega)$  is a valuation. If we represent V coalgebraically as a map  $\sigma_V : \omega \to \wp(\mathsf{P})$  (cf. Remark 1.3), then in the terminology of Definition 4.2,  $\mathbb{S}$  is indeed a  $\wp(\mathsf{P})$ -stream.

### 4.1 Deterministic stream automata

We start with the most general definition of a deterministic stream automaton.

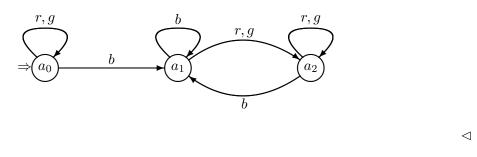

**Definition 4.4** Given an alphabet C, a deterministic C-automaton is a quadruple  $\mathbb{A} = \langle A, \delta, Acc, a_I \rangle$ , where A is a finite set,  $a_I \in A$  is the initial state of  $\mathbb{A}$ ,  $\delta : A \times C \to A$  its transition function, and  $Acc \subseteq A^{\omega}$  its acceptance condition. The pair  $\langle A, \delta \rangle$  is called the transition diagram of  $\mathbb{A}$ .

Given an automaton  $\mathbb{A} = \langle A, \delta, Acc, a_I \rangle$ , we may extend the map  $\delta : A \times C \to A$  to a map  $\widehat{\delta} : A \times C^* \to A$  by putting

$$\begin{array}{lll} \widehat{\delta}(a,\varepsilon) & := & a \\ \widehat{\delta}(a,uc) & := & \delta(\widehat{\delta}(a,u),c). \end{array}$$

We will write  $a \xrightarrow{c} a'$  if  $a' = \delta(a, c)$ , and  $a \xrightarrow{w} a'$  if  $a' = \widehat{\delta}(a, w)$ . In words,  $a \xrightarrow{w} a'$  if there is a *w*-labelled path from *a* to *a'*.

**Example 4.5** The transition diagram and initial state of a deterministic automaton can nicely be represented graphically, as in the picture below, where  $C = \{b, r, g\}$ :

An automaton comes to life if we supply it with input, in the form of a stream over its alphabet: It will *process* this stream, as follows. Starting from the initial state  $a_I$ , the automaton will step by step pass through the stream, jumping from one state to another as prescribed by the transition function.

**Example 4.6** Let  $\mathbb{A}_0$  be any automaton with transition diagram and initial state as given above, and suppose that we give this device as input the stream  $\alpha = brgbrgbrgbrgbrgbrgbrgb\cdots$ . Then we find that  $\mathbb{A}_0$  will make an infinite series of transitions, determined by  $\alpha$ :

$$a_0 \xrightarrow{b} a_1 \xrightarrow{r} a_2 \xrightarrow{g} a_2 \xrightarrow{b} a_1 \cdots$$

Thus the machine passes through an infinite sequence of states:

$$\rho = a_0 a_1 a_2 a_2 a_1 a_2 a_2 a_1 a_2 a_2 \dots$$

This sequence is called the *run* of the automaton on the word  $\alpha$  — a run of A is thus an A-stream.

For a second example, on the word  $\alpha' = brbgbrgrgrgrgrgrgr \cdots$  the run of the automaton  $\mathbb{A}_0$  looks as follows:

$$a_0 \xrightarrow{b} a_1 \xrightarrow{r} a_2 \xrightarrow{b} a_1 \xrightarrow{g} a_2 \xrightarrow{b} a_1 \xrightarrow{r} a_2 \xrightarrow{g} a_2 \xrightarrow{r} a_2 \xrightarrow{g} \cdots$$

we see that from the sixth step onwards, the machine device remains circling in its state  $a_2$ :  $\cdots a_2 \xrightarrow{r} a_2 \xrightarrow{g} a_2 \xrightarrow{r} \cdots$ .

**Definition 4.7** The *run* of an automaton  $\mathbb{A} = \langle A, \delta, Acc, a_I \rangle$  on a *C*-stream  $\gamma = c_0 c_1 c_2 \dots$  is the infinite *A*-sequence

$$\rho = a_0 a_1 a_2 \dots$$

such that  $a_0 = a_I$  and  $a_i \xrightarrow{c_i} a_{i+1}$  for every  $i \in \omega$ .

Generally, whether or not an automaton *accepts* an infinite word, depends on the existence of a successful run — note that in the present deterministic setting, this run is unique. In order to determine which runs are successful, we need the acceptance condition.

 $\triangleleft$ 

Lectures on the modal  $\mu$ -calculus

**Definition 4.8** A run  $\rho \in A^{\omega}$  of an automaton  $\mathbb{A} = \langle A, \delta, Acc, a_I \rangle$  is *successful* with respect to an acceptance condition Acc if  $\rho \in Acc$ .

An C-automaton  $\mathbb{A} = \langle A, \delta, Acc, a_I \rangle$  accepts a C-stream  $\gamma$  if the run of  $\mathbb{A}$  on  $\gamma$  is successful. The  $\omega$ -language  $L_{\omega}(\mathbb{A})$  associated with  $\mathbb{A}$  is defined as the set of streams that are accepted by  $\mathbb{A}$ . Two automata are called *equivalent* if they accept the same streams.

A natural requirement on the acceptance condition is that it only depends on a bounded amount of information about the run.

**Remark 4.9** In the case of automata running on *finite words*, there is a very simple and natural acceptance criterion. The point is that runs on finite words are themselves finite too. For instance, suppose that in Example 4.6 we consider the run on the finite word *brgb*:

$$a_0 \xrightarrow{b} a_1 \xrightarrow{r} a_2 \xrightarrow{g} a_2 \xrightarrow{b} a_1.$$

Then this runs *ends* in the state  $a_1$ . In this context, a natural criterion for the acceptance of the word *abca* by the automaton is to make it dependent on the membership of this final state  $a_1$  in a designated set  $F \subseteq A$  of *accepting* states.

A structure of the form  $\mathbb{A} = \langle A, \delta, F, a_I \rangle$  with  $F \subseteq A$  may be called a *finite word automaton*, and we say that such a structure *accepts* a finite word w if the unique state a such that  $a_I \xrightarrow{w} a$  belongs to F. The *language*  $L(\mathbb{A})$  is defined as the set of all finite words accepted by  $\mathbb{A}$ .

#### 4.2 Acceptance conditions

For runs on infinite words, a natural acceptance criterion would involve the collection of states that occur infinitely often in the run.

**Definition 4.10** Let  $\alpha : \omega \to A$  be a stream over some finite set A. Given an element  $a \in A$ , we define the *frequency* of a in  $\alpha$  as  $\#_a(\alpha) := |\{n \in \omega \mid \alpha(n) = a\}|$ . Based on this, we set  $Occ(\alpha) := \{a \in A \mid \#_a(\alpha) > 0\}$  and  $Inf(\alpha) := \{a \in A \mid \#_a(\alpha) = \omega\}$ 

In words,  $Occ(\alpha)$  and  $Inf(\alpha)$  denote the set of elements of A that occur in  $\alpha$  at least once and infinitely often, respectively.

**Definition 4.11** Given a transition diagram  $\langle A, \delta \rangle$ , we define the following types of acceptance conditions:

• A Muller condition is given as a collection  $\mathcal{M} \subseteq \wp(A)$  of subsets of A. The corresponding acceptance condition is defined as

$$Acc_{\mathcal{M}} := \{ \alpha \in A^{\omega} \mid Inf(\alpha) \in \mathcal{M} \}.$$

• A *Büchi* condition is given as a subset  $F \subseteq A$ . The corresponding acceptance condition is defined as

$$Acc_F := \{ \alpha \in A^{\omega} \mid Inf(\alpha) \cap F \neq \emptyset \}.$$

• A parity condition is given as a map  $\Omega : A \to \omega$ . The corresponding acceptance condition is defined as

$$Acc_{\Omega} := \{ \alpha \in A^{\omega} \mid \max\{\Omega(a) \mid a \in Inf(\alpha) \} \text{ is even } \}.$$

Automata with these acceptance conditions are called *Muller*,  $B\ddot{u}chi$  and *parity automata*, respectively.

Of these three types of acceptance conditions, the Muller condition perhaps is the most natural. It exactly and directly specifies the subsets of A that are admissible as the set  $Inf(\rho)$ of a successful run. The Büchi condition is also fairly intuitive: an automaton with Büchi condition F accepts a stream  $\alpha$  if the run on  $\alpha$  passes through some state in F infinitely often. This makes Büchi automata the natural analog of the automata that operate on *finite* words, see Remark 4.9.

The parity condition may be slightly more difficult to understand. The idea is to give each state a of  $\mathbb{A}$  a weight  $\Omega(a) \in \omega$ . Then any infinite A-sequence  $\alpha = a_0 a_1 a_2 \dots$  induces an infinite sequence  $\Omega(a_0)\Omega(a_1)\dots$  of natural numbers. Since the range of  $\Omega$  is finite this means that there is a *largest* natural number  $N_{\alpha}$  occurring infinitely often in this sequence,  $N_{\alpha} := \max{\{\Omega(a) \mid a \in Inf(\alpha)\}}$ . Now, a parity automaton accepts an infinite word iff the number  $N_{\rho}$  of the associated run  $\rho$  is *even*.

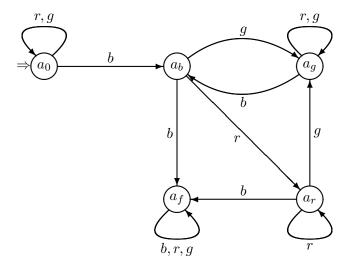

At first sight, this condition will seem rather contrived and artificial. Nevertheless, for a number of reasons the parity automaton is destined to play the leading role in these notes. Most importantly, the distinction between even and odd parities directly corresponds to that between least and greatest fixpoint operators, so that parity automata are the more direct automata-theoretic counterparts of fixpoint formulas. An additional theoretic motivation to use parity automata is that their associated acceptance games have some very nice game-theoretical properties, as we will see further on.

Let us now first discuss some examples of automata with these three acceptance conditions.

**Example 4.12** Suppose that we supply the device of Example 4.5 with the Büchi acceptance condition  $F_0 = \{a_1\}$ . That is, the resulting automaton  $\mathbb{A}_0$  accepts a stream  $\alpha$  iff the run of  $\mathbb{A}_0$  passes through the state  $a_1$  infinitely often. For instance,  $\mathbb{A}_0$  will accept the word  $\alpha = brgbrgbrgbrgbrgbrgbrgb\cdots$ , because the run of  $\mathbb{A}_0$  is the stream  $a_0a_1a_2a_2a_1a_2a_2a_1a_2a_2\ldots$  which indeed contains  $a_1$  infinitely many times. On the other hand, as we saw already, the run of  $\mathbb{A}_0$  on the stream  $\alpha' = brbgbrgrgrgrgrgrgr\cdots$  loops in state  $a_2$ , and so  $\alpha'$  will not be accepted.

In general, it is not hard to prove that  $\mathbb{A}_0$  accepts a *C*-stream  $\gamma$  iff  $\gamma$  contains infinitely many *b*'s.

**Example 4.13** Consider the automaton  $\mathbb{A}_1$  given by the following diagram and initial state:

As an example of a Muller acceptance condition, consider the set

$$\{ \{a_0\}, \{a_g\}, \{a_b, a_g\}, \{a_b, a_r, a_g\} \}$$

The resulting automaton accepts those infinite streams in which every b is followed by a finite number of r's, followed by a g. To see this, here is a brief description of the intuitive meaning of the states:

- $a_0$  represents the situation where the automaton has not encountered any b's;
- $a_f$  is the 'faulty' state;
- $a_b$  is the state where the automaton has just processed a b; it now has to pass through a finite sequence of r's, eventually followed by a g;
- $a_r$  represents the situation where the automaton, after seeing a b, has processed a finite, non-empty, sequence of r's;
- $a_g$  is the state where the automaton, after passing the last b, has fulfilled its obligation to process a g.

We leave the details of the proof as an exercise to the reader.

**Example 4.14** For an example of a parity automaton, consider the transition diagram of Example 4.5, and suppose that we endow the set  $\{a_0, a_1, a_2\}$  with the priority map  $\Omega$  given by  $\Omega(a_i) = i$ . Given the shape of the transition diagram, it then follows more or less directly from the definitions that the resulting automaton accepts an infinite word over  $C = \{b, r, g\}$  iff it either stays in  $a_0$ , or visits  $a_2$  infinitely often. From this one may derive that  $L_{\omega}(\mathbb{A})$  consists of those C-streams containing infinitely many r's or infinitely many g's (or both).

It is important to understand the relative strength of Muller, Büchi and parity automata when it comes to recognizing  $\omega$ -languages. The Muller acceptance condition is the more fundamental one in the sense that the other two are easily represented by it.

 $\triangleleft$ 

**Proposition 4.15** There is an effective procedure transforming a deterministic Büchi stream automaton into an equivalent deterministic Muller stream automaton.

**Proof.** Given a Büchi condition F on a set A, define the corresponding Muller condition  $\mathcal{M}_F \subseteq \wp(A)$  as follows:

$$\mathcal{M}_F := \{ B \subseteq A \mid B \cap F \neq \emptyset \}.$$

Clearly then,  $Acc_{\mathcal{M}_F} = Acc_F$ . It is now immediate that any Büchi automaton  $\mathbb{A} = \langle A, \delta, F, a_I \rangle$ is equivalent to the Muller automaton  $\langle A, \delta, \mathcal{M}_F, a_I \rangle$ . QED

**Proposition 4.16** There is an effective procedure transforming a deterministic parity stream automaton into an equivalent deterministic Muller stream automaton.

**Proof.** Analogous to the proof of the previous proposition, we put

$$\mathcal{M}_{\Omega} := \{ B \subseteq A \mid \max(\Omega[B]) \text{ is even } \},\$$

and leave it for the reader to verify that this is the key observation in turning a parity acceptance condition into a Muller one. QED

Interestingly enough, Muller automata can be simulated by devices with a parity condition.

**Proposition 4.17** There is an effective procedure transforming a deterministic Muller stream automaton into an equivalent deterministic parity stream automaton.

**Proof.** Given a Muller automaton  $\mathbb{A} = \langle A, \delta, \mathcal{M}, a_I \rangle$ , define the corresponding parity automaton  $\mathbb{A}' = \langle A', \delta', \Omega, a'_I \rangle$  as follows. The crucial concept used in this construction is that of *latest appearance records*. The following notation will be convenient: given a finite sequence in  $A^*$ , say,  $\alpha = a_1 \dots a_n$ , we let  $\tilde{\alpha}$  denote the set  $\{a_1, \dots, a_n\}$ , and  $\alpha[\nabla/a]$  the sequence  $\alpha$  with every occurrence of a being replaced with the symbol  $\nabla$ .

To start with, the set A' of states is defined as the collection of those finite sequences over the set  $A \cup \{\nabla\}$  in which every symbol occurs exactly once:

$$A' = \{a_1 \dots a_k \nabla a_{k+1} \dots a_m \mid m = |A| \text{ and } A = \{a_1, \dots, a_m\}\}.$$

The intuition behind this definition is that a state in  $\mathbb{A}'$  encodes information about the states of  $\mathbb{A}$  that have been visited during the initial part of its run on some word. More specifically, the state  $a_1 \ldots a_k \nabla a_{k+1} \ldots a_m$  encodes that the states visited by  $\mathbb{A}$  are  $a_{n+1}, \ldots, a_m$  (for some  $n \leq m$ , not necessarily n = k), and that of these,  $a_m$  is the state visited most recently,  $a_{m-1}$ the one before that, etc. The symbol  $\nabla$  marks the *previous* position of  $a_m$  in the list.

For a proper understanding of  $\mathbb{A}'$  we need to go into more detail. First, for the initial position of  $\mathbb{A}'$ , fix some enumeration  $d_1, \ldots, d_m$  of A with  $a_I = d_m$ , and define

$$a'_I := d_1 \dots d_m \nabla.$$

For the transition function, consider a state  $\alpha = a_1 \dots a_k \nabla a_{k+1} \dots a_m$  in A', and a color  $c \in C$ . To obtain the state  $\delta'(\alpha, c)$ , replace the occurrence of  $\delta(a_m, c)$  in  $a_1 \dots a_m$  with  $\nabla$ , and make the state  $\delta(a_m, c)$  itself the rightmost element of the resulting sequence. Thus the  $\forall$  in the new sequence marks the latest appearance of the state  $\delta(a_m, c)$ . Formally, we put

$$\delta'(a_1 \dots a_k \nabla a_{k+1} \dots a_m, c) := (a_1 \dots a_m) [\nabla / \delta(a_m, c)] \cdot \delta(a_m, c).$$

(Here we include the cases where k = 0 or k = m; these cover the situations where  $\nabla$  appears at, respectively, the beginning or the end of the word.) For an example, see 4.18 below.

Now consider the runs  $\rho$  and  $\rho'$  of  $\mathbb{A}$  and  $\mathbb{A}'$ , respectively, on some *C*-stream  $\gamma$ . Recall that  $Inf(\rho)$  denotes the set of states of  $\mathbb{A}$  that are visited infinitely often during  $\rho$ . From a certain moment on,  $\rho$  will *only* pass through states in  $Inf(\rho)$ ; let  $\mathbb{A}$  continue its run until it has passed through each state in  $Inf(\rho)$  at least one more time. It is not too hard to see that there is some l such that from that same moment t on,  $\rho'$  will only pass through states of the form  $a_1 \ldots a_k \nabla a_{k+1} \ldots a_m$  such that the states in  $Inf(\rho)$  are those that form the final segment  $a_{l+1} \ldots a_m$  of the sequence  $a_1 \ldots a_m$ .

We now arrive at the role of the special symbol  $\nabla$ . Since  $\nabla$  marks the previous position of  $a_m$ , all states occurring to its right after time t must belong to the set  $Inf(\rho)$ . In other words, we have

$$Inf(\rho') \subseteq \{ \alpha \nabla \beta \in A' \mid \beta \subseteq Inf(\rho) \}.$$

Furthermore, among the states  $\alpha \nabla \beta \in Inf(\rho')$ , the ones with the *longest tail*  $\beta$  (i.e., with maximal  $|\beta|$ ), are exactly the ones where  $Inf(\rho)$  is *identical* to  $\tilde{\beta}$ . Obviously, these will be of interest for the definition of the acceptance condition of  $\mathbb{A}'$ . To make the discussion somewhat more precise, define, for a subset Q of the state space  $A', \overline{Q} := \{\alpha \nabla \beta \in Q \mid |\tilde{\beta}'| \leq |\tilde{\beta}| \text{ for all } \alpha' \nabla \beta' \in Q\}$ . That is,  $\overline{Q}$  consists of the sequences  $\alpha \nabla \beta \in Q$  where  $\beta$  takes maximal length. Then one may show that

$$\alpha \nabla \beta \in \overline{Inf(\rho')} \text{ implies } \widetilde{\beta} = Inf(\rho).$$
(40)

This shows how to encode the success of runs of  $\mathbb{A}$  in a parity condition for  $\mathbb{A}'$ . Putting

$$\Omega(lpha 
abla eta) := \left\{ egin{array}{cc} 2 \cdot |eta| + 1 & ext{if } \widetilde{eta} 
ot \in \mathcal{M}, \ 2 \cdot |eta| + 2 & ext{if } \widetilde{eta} \in \mathcal{M}, \end{array} 
ight.$$

we ensure that the states in  $\overline{Inf(\rho')}$  receive maximal priority, and that this priority is even.

We now have the following chain of equivalences:

$$\begin{array}{ll} \mathbb{A} \text{ accepts } \gamma \\ \iff Inf(\rho) \in \mathcal{M} \\ \iff \widetilde{\beta} \in \mathcal{M} \text{ whenever } \alpha \nabla \beta \in \overline{Inf(\rho')} \\ \iff \max\{\Omega(\alpha \nabla \beta) \mid \alpha \nabla \beta \in Inf(\rho')\} \text{ is even} \\ \iff \mathbb{A}' \text{ accepts } \gamma. \end{array}$$
(definition acceptance  $\mathbb{A}'$ )

Clearly this establishes the equivalence of  $\mathbb{A}$  and  $\mathbb{A}'$ .

 $\triangleleft$ 

**Example 4.18** With  $\mathbb{A}_1$  the Muller automaton of Example 4.13, here are some examples of the transition function  $\delta'$  of its parity equivalent  $\mathbb{A}'$ :

$\delta'(a_b a_r a_g a_f a_0 \nabla, b)$	:=	$\nabla a_r a_g a_f a_0 a_b$	$\delta'(\nabla a_r a_g a_f a_0 a_b, b)$	:=	$a_r a_g \nabla a_0 a_b a_f$
$\delta'(a_b a_r a_g a_f a_0 \nabla, r)$	:=	$a_b a_r a_g a_f  abla a_0$	$\delta'(\nabla a_r a_g a_f a_0 a_b, r)$	:=	$\nabla a_g a_f a_0 a_b a_r$
$\delta'(a_b a_r a_g a_f a_0 \nabla, g)$	:=	$a_b a_r a_a a_f \nabla a_0$	$\delta'(\nabla a_r a_g a_f a_0 a_b, g)$	:=	$a_r \nabla a_f a_0 a_b a_a$

Likewise, a few examples of the priority map:

$$\begin{array}{rcl} \Omega(a_b a_r a_g a_f \bigtriangledown a_0) & := & 4 \\ \Omega(a_g a_f a_0 a_b \bigtriangledown a_r) & := & 3 \\ \Omega(a_f a_r a_0 \bigtriangledown a_b a_g) & := & 6 \\ \Omega(a_f a_0 \bigtriangledown a_b a_r a_g) & := & 8 \end{array}$$

As the initial state of  $\mathbb{A}'$ , one could for instance take the sequence  $a_r a_r a_q a_f a_0 \nabla$ .

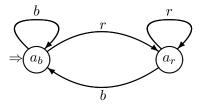

The following example shows that, in the case of deterministic stream automata, the recognizing power of Muller and parity automata is *strictly* stronger than that of Büchi automata.

**Example 4.19** Consider the following language over the alphabet  $C = \{b, r\}$ :

$$L = \{ \alpha \in C^{\omega} \mid r \notin Inf(\alpha) \}.$$

That is, L consists of those C-streams that contain at most finitely many red items (that is, the symbol r occurs at most finitely often). We will give both a Muller and a parity automaton to recognize this language, and then show that there is no Büchi automaton for L.

It is not difficult to see that there is a deterministic Muller automaton recognizing this language. Consider the automaton  $\mathbb{A}_2$  given by the following diagram,

and Muller acceptance condition  $\mathcal{M}_2 := \{\{a_b\}\}\)$ . It is straightforward to verify that the run of  $\mathbb{A}_2$  on an  $\{b, r\}\)$ -stream  $\alpha$  keeps circling in  $a_b$  iff from a certain moment on,  $\alpha$  only produces b's.

For a parity automaton recognizing L, endow the diagram above with the priority map  $\Omega_2$  given by  $\Omega_2(a_b) = 0$ ,  $\Omega_2(a_r) = 1$ . With this definition, there can only be one set of states of which the maximum priority is even, namely, the singleton  $\{a_b\}$ . Hence, this parity acceptance condition is the same as the Muller condition  $\{\{a_b\}\}$ .

However, there is no deterministic Büchi automaton recognizing L. Suppose for contradiction that  $L = L_{\omega}(\mathbb{A})$ , where  $\mathbb{A} = \langle A, \delta, F, a_I \rangle$  is some Büchi automaton. Since the stream  $\alpha_0 = bbb...$  belongs to L, it is accepted by A. Hence in particular, the run  $\rho_0$  of A on  $\alpha_0$  will pass some state  $f_0 \in F$  after a finite number, say  $n_0$ , of steps.

Now consider the stream  $\alpha_1 = b^{n_0} r b b \dots$  Since runs are uniquely determined, the initial  $n_0$  steps of the run  $\rho_1$  of  $\mathbb{A}$  on  $\alpha_1$  are identical to the first  $n_0$  steps of  $\mathbb{A}$  on  $\alpha_0$ , and so  $\rho_1$  also passes through  $f_0$  after  $n_0$  steps. But since  $\alpha_1$  belongs to L too, it too is accepted by  $\mathbb{A}$ . Thus on input  $\alpha_1$ ,  $\mathbb{A}$  will visit a state in F infinitely often. That is, we may certainly choose an  $n_1 \in \omega$  such that  $\rho_1$  passes through some state  $f_1 \in F$  after  $n_0 + n_1 + 1$  steps. Now consider the stream  $\alpha_2 = b^{n_0} r b^{n_1} r b b \dots$ , and analyze the run  $\rho_2$  of  $\mathbb{A}$  on  $\alpha_2$ . Continuing like this, we can find positive numbers  $n_0, n_1, \dots$  such that for every  $k \in \omega$ , the stream

$$\alpha_k = b^{n_0} r b^{n_1} \dots r b^{n_k} r b b b \dots \in L, \text{ for all } k.$$

$$\tag{41}$$

Consider the stream

$$\alpha = (b^{n_0}r)(b^{n_1}r)\dots(b^{n_k}r)\dots$$

Containing infinitely many r's,  $\alpha$  does not belong to L. Nevertheless, it follows from (41) that the run  $\rho$  of  $\mathbb{A}$  on  $\alpha$  passes through the states  $f_0, f_1, \ldots$  as described above. Since F is finite, there is then at least one  $f \in F$  appearing infinitely often in this sequence. Thus we have found an  $f \in F$  that is passed infinitely often by  $\rho$ , showing that  $\mathbb{A}$  accepts  $\alpha$ . This gives the desired contradiction.

**Remark 4.20** Since it is easy to see that the complement

$$\overline{L} = \{ \alpha \in C^{\omega} \mid r \in Inf(\alpha) \}$$

of the language studied in Example 4.19 is recognized by a Büchi automaton, the example also shows that the class of Büchi recognizable stream languages is not closed under taking complementations.  $\triangleleft$ 

#### 4.3 Nondeterministic automata

Nondeterministic automata generalize deterministic ones in that, given a state and a color, the next state is not *uniquely* determined, and in fact need not exist at all.

**Definition 4.21** Given an alphabet C, a nondeterministic C-automaton is a quadruple  $\mathbb{A} = \langle A, \Delta, Acc, a_I \rangle$ , where A is a finite set,  $a_I \in A$  is the initial state of  $\mathbb{A}$ ,  $\Delta : A \times C \to \wp(A)$  its transition function of  $\mathbb{A}$ , and  $Acc \subseteq A^{\omega}$  its acceptance condition.

As a consequence, the run of a nondeterministic automaton on a stream is no longer uniquely determined either.

**Definition 4.22** Given a nondeterministic automaton  $\mathbb{A} = \langle A, \Delta, Acc, a_I \rangle$ , we define the relations  $\to \subseteq A \times C \times A$  and  $\twoheadrightarrow \subseteq A \times C^* \times A$  in the obvious way:  $a \stackrel{c}{\to} a'$  if  $a' \in \Delta(a, c)$ ,  $a \stackrel{\varepsilon}{\twoheadrightarrow} a'$  if a = a', and  $a \stackrel{wc}{\twoheadrightarrow} a'$  if there is a a'' such that  $a \stackrel{w}{\twoheadrightarrow} a'' \stackrel{c}{\to} a'$ . A run of a nondeterministic automaton  $\mathbb{A} = \langle A, \Delta, Acc, a_I \rangle$  on an C-stream  $\gamma = c_0 c_1 c_2 \dots$  is an infinite A-sequence

$$\rho = a_0 a_1 a_2 \dots$$

such that  $a_0 = a_I$  and  $a_i \stackrel{c_i}{\to} a_{i+1}$  for every  $i \in \omega$ .

 $\triangleleft$ 

Now that runs are no longer unique, an automaton may have both successful and unsuccessful runs on a given stream. Consequently, there is a choice to make concerning the definition of the notion of acceptance.

**Definition 4.23** A nondeterministic *C*-automaton  $\mathbb{A} = \langle A, \Delta, Acc, a_I \rangle$  accepts a *C*-stream  $\gamma$  if there is a successful run of  $\mathbb{A}$  on  $\gamma$ .

Further concepts, such as the language recognized by an automaton, the notion of equivalence of two automata, and the Büchi, Muller and parity acceptance conditions, are defined as for deterministic automata. Also, the transformations given in the Propositions 4.15, 4.16 and 4.17 are equivalence-preserving for nondeterministic automata just as for deterministic one. *Different* from the deterministic case, however, is that *nondeterministic* Büchi automata have the *same* accepting power as their Muller and parity variants.

**Proposition 4.24** There is an effective procedure transforming a nondeterministic Muller stream automaton into an equivalent nondeterministic Büchi stream automaton.

**Proof.** Let  $\mathbb{A} = \langle A, \Delta, \mathcal{M}, a_I \rangle$  be a nondeterministic Muller automaton. The idea underlying the definition of the Büchi equivalent  $\mathbb{A}'$  is that  $\mathbb{A}'$ , while copying the behavior of  $\mathbb{A}$ , guesses the set  $M = Inf(\rho)$  of a successful run of  $\mathbb{A}$ , and at a certain (nondeterministically chosen) moment confirms this choice by moving to a position of the form  $(a, M, \emptyset)$ . In order to make sure that not too many streams are accepted, the device has to keep track which of the states in M have been visited by  $\mathbb{A}$ , resetting this counter to the empty set every time when all M-states have been passed.

In some more detail,  $\mathbb{A}'$  consists of a copy of  $\mathbb{A}$ , together with, for every set  $M \in \mathcal{M}$ , a part  $\mathbb{A}_M$  which, roughly spoken, corresponds to a copy of  $\mathbb{A}$  from which all states outside of M have been removed, and whose states record the part of M that recently has been visited.

$$\begin{array}{rcl} A' &:=& A \cup \bigcup_{M \in \mathcal{M}} \left\{ (a, M, P) \mid a \in M, P \subseteq M \right\}, \\ a'_I &:=& a_I \\ \Delta'(a, c) &:=& \Delta(a, c) \cup \bigcup_{M \in \mathcal{M}} \left\{ (b, M, \varnothing) \mid b \in \Delta(a, c) \cap M \right\} \\ \Delta'((a, M, P), c) &:=& \left\{ \begin{array}{ll} \left\{ (b, M, P \cup \{a\}) \mid b \in \Delta(a, c) \cap M \right\} & \text{if } P \cup \{a\} \neq M \\ \left\{ (b, M, \varnothing) \mid b \in \Delta(a, c) \cap M \right\} & \text{if } P \cup \{a\} = M \end{array} \right. \\ F &:=& \bigcup_{M \in \mathcal{M}} \left\{ (a, M, P) \in A' \mid P = \varnothing \right\}. \end{array}$$

We leave it as an exercise for the reader to verify that the resulting automaton is indeed equivalent to  $\mathbb{A}$ . QED

We now turn to the *determinization* problem for stream automata. In the case of automata operating on finite words, it is not difficult to prove that nondeterminism does not really add recognizing power: any nondeterministic automaton  $\mathbb{A}$  may be 'determinized', that is, transformed into an equivalent deterministic automaton  $\mathbb{A}^d$ .

**Remark 4.25** Finite word automata (see Example 4.9) can be determinized by a fairly simple *subset construction*.

Let  $\mathbb{A} = \langle A, \Delta, F, a_I \rangle$  be a nondeterministic word automaton. A run of  $\mathbb{A}$  on a finite word  $w = c_1 \cdots c_n$  is defined as a finite sequence  $a_0 a_1 \cdots a_n$  such that  $a_0 = a_I$  and  $a_i \stackrel{c_i}{\to} a_{i+1}$  for all i < n.  $\mathbb{A}$  accepts a finite word w if there is a successful run, that is, a run  $a_0 a_1 \cdots a_n$  ending in an accepting state  $a_n$ .

Given such a nondeterministic automaton, define a deterministic automaton  $\mathbb{A}^+$  as follows. For the states of  $\mathbb{A}^+$  we take the *macro-states* of  $\mathbb{A}$ , that is, the nonempty subsets of A. The deterministic transition function  $\delta$  is given by

$$\delta(P,c) := \bigcup_{a \in P} \Delta(a,c).$$

In words,  $\delta(P, c)$  consists of those states that can be reached from some state in P by making one *a*-step in  $\mathbb{A}$ . The accepting states of  $\mathbb{A}^+$  are those macro-states that contain an accepting state from  $\mathbb{A}$ :  $F^+ := \{P \in A^+ \mid P \cap F \neq \emptyset\}$ , and its initial state is the singleton  $\{a_I\}$ .

In order to establish the equivalence of  $\mathbb{A}$  and  $\mathbb{A}^+$ , we need to prove that for every word w,  $\mathbb{A}$  has an accepting run on w iff the unique run of  $\mathbb{A}^+$  on w is successful. The key claim in this proof is the following statement:

$$\widehat{\delta}(\{a_I\}, w) = \{a \in A \mid a_I \xrightarrow{w}_{\mathbb{A}} a\}.$$
(42)

stating that  $\hat{\delta}(\{a_I\}, w)$  consists of all the states that  $\mathbb{A}$  can reach from  $a_I$  on input w. We leave the straightforward inductive proof of (42) as an exercise for the reader.

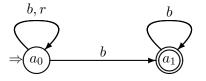

The equivalence of  $\mathbb{A}$  and  $\mathbb{A}^+$  then follows by the following chain of equivalences, for any finite word w:  $\mathbb{A}^+$  accepts w iff  $\widehat{\delta}(\{a_I\}, w) \in F^+$  iff  $\widehat{\delta}(\{a_I\}, w) \cap F \neq \emptyset$  iff  $a_I \xrightarrow{w}_{\mathbb{A}} a$  for some  $a \in F$  iff  $\mathbb{A}$  accepts w.

Unfortunately, the class of Büchi automata does not admit such a determinization procedure. As a consequence of Proposition 4.24 above, and witnessed by the Examples 4.19 and 4.26, the recognizing power of nondeterministic Büchi automata is strictly greater than that of their deterministic variants.

**Example 4.26** For a nondeterministic Büchi automaton recognizing the language

$$L = \{ \alpha \in C^{\omega} \mid r \notin Inf(\alpha) \}$$

of Example 4.19, consider the automaton given by the following picture:

In general, the Büchi acceptance condition  $F \subseteq A$  of an automaton  $\mathbb{A}$  is depicted by the set of states with *double circles*. So in this case,  $F = \{a_1\}$ .

There is positive news as well. A key result in automata theory states that when we turn to Muller and parity automata, nondeterminism does *not* increase recognizing power. This result follows from Proposition 4.24 and Theorem 4.27 below.

**Theorem 4.27** There is an effective procedure transforming a nondeterministic Büchi stream automaton into an equivalent deterministic Muller stream automaton.

The *proof* of Theorem 4.27 will be given in the next section. As an important corollary we mention the following *Complementation Lemma*.

**Proposition 4.28** Let  $\mathbb{A}$  be a nondeterministic Muller or parity automaton. Then there is an automaton  $\overline{\mathbb{A}}$  of the same kind, such that  $L_{\omega}(\overline{\mathbb{A}})$  is the complement of the language  $L_{\omega}\mathbb{A}$ .

Leaving the proof of this proposition as an exercise for the reader, we finish this section with a summary of the relative power of the automata concept in the diagram below. Arrows indicate the reducibility of one concept to another, 'D' and 'ND' are short for 'deterministic' and 'nondeterministic', respectively.

D Büchi	$\Rightarrow$	D Muller	$\iff$	D parity
$\Downarrow$		$\updownarrow$		$\uparrow$
ND Büchi	$\iff$	ND Muller	$\iff$	ND parity

Having established these equivalences we naturally arrive at the following definition.

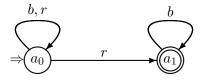

**Definition 4.29** Let *C* be a finite set. A *C*-stream language  $L \subseteq C^{\omega}$  is called  $\omega$ -regular if there exists a *C*-stream automaton  $\mathbb{A} = (A, \Delta, \Omega, a_I)$  such that  $L = L_{\omega}(\mathbb{A})$ , where  $\mathbb{A}$  is either a (deterministic/nondeterministic) Muller or parity automaton, or a nondeterministic Büchi automaton.

#### 4.4 Determinization of stream automata

This section is devoted to the proof of Theorem 4.27, which is based on a modification of the subset construction of Remark 4.25.

▶ more information on determinization/simulation to be supplied

**Remark 4.30** This modification will have to be fairly substantial: As we will see now, Theorem 4.27 cannot be proved by a straightforward adaptation of the subset construction discussed in Remark 4.25. Consider the Büchi automaton A given by the following picture:

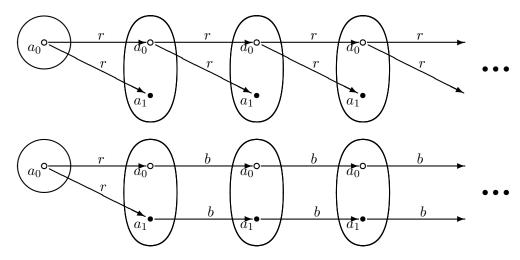

We leave it for the reader to verify that  $L_{\omega}(\mathbb{A})$  consists of those streams of bs and rs that contain at least one and at most finitely many red items. In particular, the stream  $r^{\omega} = rrrrrr...$  is rejected, while the stream  $rb^{\omega} = rbbbb...$  is accepted.

Now consider a deterministic automaton  $\mathbb{A}^+$  of which the transition diagram is given by the subset construction. Then the run of the automaton  $\mathbb{A}^+$  on  $r^{\omega}$  is *identical* to its run on  $rb^{\omega}$ :

 $a_0\{a_0, a_1\}\{a_0, a_1\}\{a_0, a_1\}\dots$ 

In other words, no matter which acceptance condition we give to  $\mathbb{A}^+$ , the automaton will accept either both  $r^{\omega}$  and  $rb^{\omega}$ , or neither. In either case  $L_{\omega}(\mathbb{A}^+)$  will be different from  $L_{\omega}(\mathbb{A})$ .

As a matter of fact, it will be instructive to see in a bit more detail how the runs of  $\mathbb{A}$  on  $r^{\omega}$  and  $rb^{\omega}$ , respectively, appear as 'traces' in the run of  $\mathbb{A}^+$  on these two streams:

Clearly, where the second run contains one single trace that corresponds to a successful run of the automaton  $\mathbb{A}$ , in the first run, all traces that reach a successful state are aborted immediately. These two pictures clarify the subtle but crucial distinctions that get lost if we try to determinize via a straightforward subset construction.

In Safra's modification of the subset construction, the states of the deterministic automaton are *finite, structured collections of macro-states*; more specifically, if we order these macro-states by the inclusion relation we obtain a certain tree structure. The key idea underlying this modification is that at each step of the run, those elements of a macro-state that are accepting (i.e., members of the Büchi set of the original automaton), will be given some special treatment. Ultimately this enables one to single out the runs with a sequence of macro-states containing a good trace (that is, an infinite sequence of states constituting an accepting run of the nondeterministic automaton).

For the formal definition of Safra trees, we recall that we call two distinct nodes in a tree are called *siblings* if they have the same parent, and that, where  $\triangleleft$  denotes the parent-child relation, its transitive closure denotes the ancestor/descendant relation. That is, if  $s \triangleleft^+ t$  we call s a *descendant* of t, and t an *ancestor* of s. Furthermore, we recall that, where s and t are distinct nodes that are not related by the ancestor/descendant relation, there is a unique pair of siblings (s', t') such that s and t are either equal to or descendants of, respectively, s' and t'; we call this pair the *ancestral* sibling pair of (s, t).

**Definition 4.31** An ordered tree is a structure  $\langle S, r, \triangleleft, <_H \rangle$  such that  $\langle S, \triangleleft \rangle$  is a tree with root  $r; \triangleleft$  is the 'child-of' relation, with  $s \triangleleft t$  denoting that s is a child of t; and  $<_H$  is a *sibling* ordering relation, that is, a strict partial order on S that totally orders the children of every node; if  $s <_H t$  we may say that s is older than t. Given two distinct nodes s and t such that neither  $s \triangleleft^* t$  nor  $t \triangleleft^* s$ , we say that s is to the left of t if the unique ancestral sibling pair (s', t') of (s, t) is such that  $s' <_H t'$ .

A Safra tree over a set B is a pair (S, L) where S is a finite ordered tree, and  $L : S \to \wp^+(B)$  is a labelling assigning a non-empty macrostate L(s) to every node s in such a way that (i) for every node s, the set  $\bigcup \{L(t) \mid t \triangleleft s\}$  is a proper subset of L(s), and (ii)  $L(s) \cap L(t) = \varnothing$  if s and t are siblings.

It is not hard to see that for any Safra tree (S, L) and for every state  $b \in B$ , b belongs to some label set of the tree iff it belongs to the label of the root. And, if b belongs to the label of the root, then there is a *unique* node  $s \in S$ , the so-called *lowest node of b*, such that  $b \in L(s)$  but s has no child t with  $b \in L(t)$ . From these observations one easily derives that

$$|S| \le |B|,\tag{43}$$

for every Safra tree over the set B.

We now turn to the details of the Safra construction.

**Definition 4.32** Let  $\mathbb{B}$  be a nondeterministic Büchi automaton  $\mathbb{B} = \langle B, b_I, \Delta, F \rangle$ . We will define a deterministic Muller automaton  $\mathbb{B}^S = \langle B^S, a_I, \delta, \mathcal{M} \rangle$ .

Assume that B has n states, and let  $N := \{1, \ldots, 2n\}$ ; we will think of N as the set of *(potential) nodes* of a Safra tree. The carrier  $B^S$  will consist of the collection of all *colored Safra trees* over B, that is, all triples  $(S, L, \theta)$  such that (S, L) is a Safra tree over B with  $S \subseteq N$ , and  $\theta$  is a map coloring nodes of the tree either white or green. The initial state of  $\mathbb{B}^S$  will be the Safra tree consisting of a single white node 1 labelled with the singleton  $\{b_I\}$ .

For the transition function on  $B^S$ , take an arbitrary colored Safra tree  $(S, L, \theta)$ . On input  $c \in C$ , the deterministic transition function  $\delta$  on  $B^S$  transforms  $(S, L, \theta)$  into a new colored, labelled Safra tree, by performing the sequence of actions below. (Note that at intermediate stages of this process, the structures may violate the conditions of Safra trees.)

- 1. Make macro-move Apply the power set construction to the individual nodes: for each node s, replace its label  $L(s) \subseteq B$  with the set  $L'(s) := \bigcup_{a \in L(s)} \Delta(a, c)$ .
- 2. Separate accepting states For each node  $s \in S$  such that L'(s) contains accepting states, add a new<sup>3</sup> node  $s' \in N \setminus S$  to S as the youngest child of s, and label s' with the set  $L'(s') := L'(s) \cap F$ . (Such an s' can be canonically chosen as the smallest  $n \in N$  such that  $n \notin S$ ).

<sup>&</sup>lt;sup>3</sup>Observe that by (43) and the definition of N, there will always be sufficiently many nodes in N such that at least one element of N is left as a 'spare' node, possibly to be used at a later stage.

- 3. Merge traces For each node s, remove those members from its label that already belong to the label of a state to the left of s (3a). After that remove all nodes with empty labels (3b).
- 4. Mark successful nodes For each (remaining) node s of which the label is *identical* to the union of the labels of its children, remove all proper descendants of s, and mark s by coloring it green. All other nodes are colored white.

For the Muller acceptance condition  $\mathcal{M}$  of  $\mathbb{B}^S$ , put  $M \in \mathcal{M}$  if there is some  $s \in \{0, \ldots, 2n\}$ such that s is present as a node of every tree in M, and s is colored green in some tree in M.

The following proposition states that the size of the Safra automaton is exponentially bounded.

**Proposition 4.34** Let  $\mathbb{B}$  be a nondeterministic Büchi automaton with n states. Then  $|\mathbb{B}^S|$  has at most  $2^{\mathcal{O}(n*\log(n))}$  states.

**Proof.** We will prove the Proposition by showing there are at most  $(2n+1)^{7n}$  coloured Safra trees over a set *B* of size *n*. For this purpose we represent coloured Safra trees in terms of functions. Recall that  $N = \{1, \ldots, 2n\}$  denotes the set of (potential) nodes of a Safra tree.

- To start with, the parent relation  $\triangleleft$  of a Safra tree can be represented by a *parent* function  $p: N \to N \cup \{0\}$  which maps every non-root node in the tree to its unique parent, and every other element of N to 0. There are at most  $(2n+1)^{2n}$  of such maps.
- Similarly, the sibling order  $<_H$  can be represented by a map from  $N \to N \cup \{0\}$  which maps any node which has older siblings to the youngest of these, and every other node to 0. Again, there at most  $(2n+1)^{2n}$  of such maps.
- The macro-state labelling L of a Safra can be represented by the function  $m : B \to N \cup \{0\}$  which maps a state  $b \in B$  to 0 if  $b \notin L(r)$  (i.e., b is not present in the Safra tree), and to the unique-lowest node s in the tree such that  $b \in L(s)$ , otherwise. The number of these maps is therefore bounded by  $(2n + 1)^n$ .
- Finally, for reasons of similarity, the colouring map  $\theta$  can be represented as a map from N to  $N \cup \{0\}$  which maps  $s \in N$  to 0 if it coloured green, and to 1 if it is either white or not present in the tree. Hence there are at most  $(2n+1)^{2n}$  of such maps.

Every coloured Safra tree can thus be represented as a quadruple of maps from either N or B to  $N \cup \{0\}$ , and so the number of these trees is bounded by  $(2n+1)^{2n} * (2n+1)^{2n} * (2n+1)^{2n} * (2n+1)^{2n} = (2n+1)^{7n}$ . QED

It is obvious from the construction that  $\mathbb{B}^S$  is a deterministic automaton, so what is left of the proof of Theorem 4.27 is to establish the equivalence of  $\mathbb{B}$  and  $\mathbb{B}^S$ .

 $\triangleleft$ 

**Proposition 4.35** Let  $\mathbb{B}$  be a nondeterministic Büchi automaton. Then

$$L_{\omega}(\mathbb{B}) = L_{\omega}(\mathbb{B}^S).$$

**Proof.**(Sketch) For the inclusion  $\subseteq$ , assume that there is a successful run  $\rho = b_0 b_1 \dots$  of  $\mathbb{B}$  on some *C*-stream  $\gamma = c_0 c_1 \dots$ . Consider the (unique) run  $\sigma = (S_0, L_0, \theta_0)(S_1, L_1, \theta_1) \dots$  of  $\mathbb{B}^S$  on  $\gamma$ . Here each  $(S_i, L_i, \theta_i)$  is a Safra tree with labeling  $L_i$  and coloring  $\theta_i$ . We claim that there is an object *s* which after some initial phase belongs to each Safra tree of  $\sigma$ , and which is marked green infinitely often. The basic idea underlying the proof of this claim is to 'follow' the run  $\rho$  as a trace through the successive trees of  $\sigma$ .

First note that at every stage *i*, the state  $b_i$  of  $\rho$  belongs to the label  $L_i(r_i)$  of the root  $r_i$  of the Safra tree  $S_i$ . It follows that the root always has a non-empty label, and hence it is never removed; thus we have  $r_0 = r_1 = \ldots$ , and so, with  $r := r_0$ , we have already found a node *r* such that *r* is present in every Safra tree in  $Inf(\sigma)$ . Now if *r* is colored green infinitely often, we are done.

So suppose that this is not the case. In other words, after a certain moment i, r will no longer be marked. Since  $\rho = (b_i)_{i \in \omega}$  is by assumption a successful run of  $\mathbb{B}$ , it passes infinitely often through a successful state. Hence we may consider the first time j > i for which  $b_j$  is an accepting state. But if  $b_j \in F$ , then in step 2 of stage j it has been put in the label set of a new child, say, s, of r. In step 3a,  $b_j$  may be removed from the label set of s, but only in case it was already present in the label set of an older sibling of s. It is not hard to see that in step 3b or 4,  $b_j$  will not be removed from the label sets it belongs to after step 3a.

We claim that in fact

for all 
$$k \ge j$$
,  $b_k \in L_k(s_k)$ , for some child  $s_k$  of  $r$ . (44)

The proof of this claim rests on the observation that  $b_k$  can only fail to be a member of the set  $\bigcup \{L_k(s) \mid s \triangleleft_k r\}$  in case r is a successful node in  $S_k$ , and we assumed that this was not the case. (Here  $\triangleleft_k$  denotes the child relation in the Safra tree  $S_k$ .) Now note that the merging of traces (as described in step 3a of the procedure) may cause states to be moved to the label set of a sibling, but only to an older one. Such a shift can thus only happen finitely often, so that after some stage  $j_1$  there is a node s such that

for all 
$$k > j_1$$
:  $s \in S_k, s \triangleleft_k r$ , and  $b_k \in L_k(s)$ . (45)

We can now repeat the argument with this s taking the role of r: either s itself is marked green infinitely often, or eventually, at some stage l, the  $\rho$ -state  $b_l \in F$  will be placed at the next level, and remain there. Since the depth of the Safra trees involved is bounded, there must be some node s which after some initial phase belongs to each Safra tree in  $\sigma$ , and which is marked infinitely often.

For the opposite inclusion  $\supseteq$ , suppose that the (unique) run  $\sigma = (S_0, L_0, \theta_0)(S_1, L_1, \theta_1) \dots$ of  $\mathbb{B}^S$  on the input stream  $\gamma = c_0 c_1 \dots$  is successful. Then by definition there is some node  $s \in N = \{0, \dots, 2n\}$  which after some initial phase will belong to each Safra tree in  $\sigma$  and which will subsequently be marked green infinitely often, say at the stages  $k_1 < k_2 < \dots$ . For each i > 0, let  $A_i$  denote the macro-state of s at stage  $k_i$ , that is:  $A_i := L_{k_i}(s)$ . For natural numbers p and q, let  $\gamma[p,q)$  denote the finite word  $c_p \cdots c_{q-1}$ , so that  $\gamma$  is equal to the infinite concatenation

$$\gamma = \gamma[0, k_1) \cdot \gamma[k_1, k_2) \cdot \gamma[k_2, k_3) \cdots$$

Since our construction is a refinement of the standard subset construction of Remark 4.25, by (42) it easily follows from the definitions of  $\delta$  that for every state  $a \in A_1$  there is a  $\gamma[0, k_1)$ -labeled path from  $b_I$  to a, or briefly:

for all 
$$a \in A_1$$
 we have  $b_I \xrightarrow{\gamma[0,k_1)} a$ . (46)

With a little more effort, crucially involving the conditions for marking nodes, and the rules governing the creation and maintenance of nodes, one may prove that

for all 
$$i > 0$$
 and for all  $a \in A_{i+1}$  there is an  $a' \in A_i$  such that  $a' \xrightarrow{\gamma[k_i, k_{i+1})}{\twoheadrightarrow_F} a.$  (47)

Here  $a' \xrightarrow{\gamma[k_i,k_{i+1})}{\twoheadrightarrow_F} a$  means that there is a  $\gamma[k_i,k_{i+1})$ -labelled path from a' to a which passes through some state in F. Details of this proof are left as an exercise to the reader.

The remainder of the proof consists of finding a successful run of  $\mathbb{B}$  on  $\gamma$  as the concatenation of a run segment given by (46) and infinitely many run segments given by (47). For this we use König's Lemma.

Defining  $A_0 := \{b_I\}$ , we will construct a tree, all of whose nodes are pairs of the form (a, i) with  $a \in A_i$ . As the (unique) parent of a node (a, i + 1) we pick one of the pairs (a', i) given by (46) (in case i = 0) or (47) (in case i > 0). Obviously this is a well-formed, infinite, finitely branching tree. So by König's Lemma, there is an infinite branch  $(a_0, 0)(a_1, 1) \cdots$ . By construction, we have  $a_0 = b_I$ , while for each  $i \ge 0$  there is a  $\gamma[k_i, k_{i+1})$ -labelled path in  $\mathbb{B}$  from  $a_i$  to  $a_{i+1}$  which passes through some accepting state of  $\mathbb{B}$ . The infinite concatenation of these paths gives a run of  $\mathbb{B}$  on  $\gamma$ , which visits infinitely often an accepting state of  $\mathbb{B}$ , and hence by finiteness of B, it visits some state of  $\mathbb{B}$  infinitely often. Clearly then this run is accepting.

#### 4.5 Logic and automata

- ▶ discuss the relation between stream automata, the linear  $\mu$ -calculus, and monadic second-order logic;
- ▶ discuss linear time logic

#### 4.6 A coalgebraic perspective

In this section we introduce a coalgebraic perspective on stream automata. We have two reasons for doing so. First, we hope that this coalgebraic presentation will facilitate the introduction, further on, of automata operating on different kinds of structures. And second, we also believe that the coalgebraic perspective, in which the similarities between automata and the objects they classify comes out more clearly, makes it easier to understand some of the fundamental concepts and results in the area.

In this context, it makes sense to consider a slightly wider class than streams only.

**Definition 4.36** A *C*-flow is a pair  $S = \langle S, \sigma \rangle$  with  $\sigma : S \to C \times S$ . Often we will write  $\sigma(s) = (\sigma_C(s), \sigma_0(s))$ . If we single out an (initial) state  $s_0 \in S$  in such a structure, we obtain a pointed *C*-flow  $(S, s_0)$ .

**Example 4.37** Streams over an alphabet C can be seen as pointed C-flows: simply identify the word  $\gamma = c_0 c_1 c_2 \dots$  with the pair  $(\langle \omega, \lambda n.(c_n, n+1) \rangle, 0)$ . Conversely, with any pointed flow  $\langle \mathbb{S}, s \rangle$  we may associate a unique stream  $\gamma_{\mathbb{S},s}$  by inductively defining  $s_0 := s, s_{i+1} := \sigma_0(s_i)$ , and putting  $\gamma_{\mathbb{S}}(n) := \sigma_C(s_n)$ .

It will be instructive to define the following notion of equivalence between flows. As its name already indicates, we are dealing with the analog of the notion of a bisimulation between two Kripke models. Since flows, having a deterministic transition structure, are less complex objects than Kripke models, the notion of bisimulation is also, and correspondingly, simpler.

**Definition 4.38** Let S and S' be two C-flows. Then a nonempty relation  $Z \subseteq S \times S'$  is a *bisimulation* if the following holds, for every  $(s, s') \in Z$ :

(color)  $\sigma_C(s) = \sigma'_C(s');$ (successor)  $(\sigma_0(s), \sigma'_0(s')) \in Z.$ 

Two pointed flows  $(\mathbb{S}, s)$  and  $(\mathbb{S}', s')$  are called *bisimilar*, notation:  $\mathbb{S}, s \nleftrightarrow \mathbb{S}', s'$  if there is some bisimulation Z linking s to s'. In case the flows  $\mathbb{S}$  and  $\mathbb{S}'$  are implicitly understood, we may drop reference to them and simply call s and s' bisimilar.

As an example, it is not hard to see that any pointed flow (S, s) is bisimilar to the stream  $\gamma_{S,s}$  that we may associate with it (see Example 4.37). Restricted to the class of streams, bisimilarity means *identity*.

**Definition 4.39** A stream is called *regular* if it is bisimilar to a finite pointed flow.  $\triangleleft$ 

Associated is a new perspective on nondeterministic stream automata which makes them very much *resemble* these flows. Roughly speaking the idea is this. Think of establishing a bisimulation between two pointed flows in terms of one structure  $\langle A, a_I, \alpha \rangle$  classifying the other,  $\langle S, s_C, \sigma \rangle$ .

Now on the one hand make a restriction in the sense that the classifying flow must be finite, but on the other hand, instead of demanding its transition function to be of the form  $\alpha : A \to C \times A$ , allow objects  $\alpha(a)$  to be *sets* of pairs in  $C \times A$ , rather than single pairs. That is, introduce *non-determinism* by letting the transition map  $\Delta$  of  $\mathbb{A}$  be of the form

$$\Delta: A \to \wp(C \times A). \tag{48}$$

**Remark 4.40** This presentation (48) of nondeterminism is completely *equivalent* to the one given earlier. The point is that there is a natural bijection between maps of the above kind, and the ones given in Definition 4.21 as the transition structure of nondeterministic automata:

$$A \to \wp(C \times A) \cong (A \times C) \to \wp(A). \tag{49}$$

To see why this is so, an easy proof suffices. Using the principle of currying we can show that

$$A \to ((C \times A) \to 2) \cong (A \times C \times A) \to 2 \cong (A \times C) \to (A \to 2),$$

where the first and last set can be identified with respectively the left and right hand side of (49) using the bijection between subsets and their characteristic functions.

Concretely, we may identify a map  $\Delta : (A \times C) \to \wp(A)$  with the map  $\Delta' : A \to \wp(C \times A)$  given by

$$\Delta'(a) := \{ (c, a') \mid a' \in \Delta(a, c) \}.$$
(50)

 $\triangleleft$ 

Thus we arrive at the following reformulation of the definition of nondeterministic automata. Note that with this definition, a stream automaton can be seen as a kind of 'multistream' in the sense that every state harbours a *set* of potential 'local realizations' as a flow. Apart from this, an obvious difference with flows is that stream automata also have an acceptance condition.

**Definition 4.41** A nondeterministic C-stream automaton is a quadruple  $\mathbb{A} = \langle A, \Delta, Acc, a_I \rangle$ such that  $\Delta : A \to \wp(C \times A)$  is the transition function,  $Acc \subseteq A^{\omega}$  is the acceptance condition, and  $a_I \in A$  is the initial state of the automaton.

Finally, it makes sense to formulate the notion of an automaton *accepting* a flow in terms that are related to that of establishing the existence of a bisimulation. The nondeterminism can nicely be captured in game-theoretic terms — note however, that here we are dealing with a single player only.

In fact, bisimilarity between two pointed flows can itself be captured game-theoretically, using a trivialized version of the bisimilarity game for Kripke models of Definition 1.26. Consider two flows A and S. Then the *bisimulation game*  $\mathcal{B}(\mathbb{A}, \mathbb{S})$  between A and S is defined as a board game with positions of the form  $(a, s) \in A \times S$ , all belonging to  $\exists$ . At position (a, s), if a and s have a different color,  $\exists$  loses immediately; if on the other hand  $\alpha_C(a) = \sigma_C(s)$ , then as the next position of the match she 'chooses' the pair consisting of the successors of a and s, respectively. These rules can concisely be formulated as in the following Table:

Position	Player	Admissible moves
$(a,s) \in A \times S$	Э	$\{(\alpha_0(a), \sigma_0(s)) \mid \alpha_C(a) = \sigma_C(s)\}$

Finally, the winning conditions of the game specify that  $\exists$  wins all infinite games. We leave it for the reader to verify that a pair  $(a, s) \in A \times S$  is a winning position for  $\exists$  iff a and s are bisimilar.

In order to proceed, however, we need to make a slight modification. We add positions of the form  $(\alpha, s) \in (C \times A) \times S$ , and insert an 'automatic' move immediately after a basic position, resulting in the following Table.

Position	Player	Admissible moves
$(a,s) \in A \times S$	-	$\{(\alpha(a),s)\}$
$(\alpha, s) \in (C \times A) \times S$	Ξ	$\{(\alpha_0, \sigma_0(s)) \mid \alpha_C = \sigma_C(s)\}$

The acceptance game of a nondeterministic automaton  $\mathbb{A}$  and a flow  $\mathbb{S}$  can now be formulated as a natural generalization of this game.

**Definition 4.42** Given a nondeterministic *C*-stream automaton  $\mathbb{A} = \langle A, a_I, \Delta, Acc \rangle$  and a pointed flow  $\mathbb{S} = \langle S, s_0, \sigma \rangle$ , we now define the *acceptance game*  $\mathcal{A}(\mathbb{A}, \mathbb{S})$  as the following board game.

Position	Player	Admissible moves
$(a,s) \in A \times S$	Э	$\{(\alpha, s) \in (C \times A) \times S \mid \alpha \in \Delta(a)\}$
$(\alpha, s) \in (C \times A) \times S$	Э	$\{(\alpha_0, \sigma_0(s)) \mid \alpha_C = \sigma_C(s)\}$

Table 8: Acceptance game for nondeterministic stream automata

Its positions and rules are given in Table 7, whereas the winning conditions of infinite matches are specified as follows. Given an infinite match of this game, first select the sequence

$$(a_0, s_0)(a_1, s_1)(a_2, s_2)\dots$$

of *basic positions*, that is, the positions reached during play that are of the form  $(a, s) \in A \times S$ . Then the match is winning for  $\exists$  if the 'A-projection'  $a_0a_1a_2...$  of this sequence belongs to Acc.

**Definition 4.43** A nondeterministic *C*-stream automaton  $\mathbb{A} = \langle A, a_I, \Delta, Acc \rangle$  accepts a pointed flow  $\mathbb{S} = \langle S, s_0, \sigma \rangle$  if the pair  $(a_I, s_0)$  is a winning position for  $\exists$  in the game  $\mathcal{A}(\mathbb{A}, \mathbb{S})$ .

The following proposition states that the two ways of looking at nondeterministic automata are equivalent.

**Proposition 4.44** Let  $\mathbb{A} = \langle A, a_I, \Delta, Acc \rangle$ , with  $\Delta : (A \times C) \to \wp(A)$  be a nondeterministic *C*-automaton, and let  $\mathbb{A}'$  be the nondeterministic *C*-stream automaton  $\langle A, a_I, \Delta', Acc \rangle$ , where  $\Delta' : A \to \wp(C \times A)$  is given by (50). Then  $\mathbb{A}$  and  $\mathbb{A}'$  are equivalent.

In the sequel we will *identify* the two kinds of nondeterministic automata, speaking of the *coalgebraic presentation*  $\langle A, a_I, \Delta' : A \to \wp(C \times A), Acc \rangle$  of an automaton  $\langle A, a_I, \Delta : (A \times C) \to \wp(A), Acc \rangle$ .

#### Notes

The idea to use finite automata for the classification of infinite words originates with Büchi. In [4] he used stream automata with (what we now call) a Büchi acceptance condition to prove the decidability of the second-order theory of the natural numbers (with the successor relation). In the subsequent development of the theory of stream automata, other acceptance conditions were introduced. The Muller condition is named after the author of [15]. The invention of the parity condition, which can be seen as a refinement of the Rabin condition, is usually attributed to Emerson & Jutla [6], Mostowski [14], and/or Wagner. The first construction of a deterministic equivalent to a nondeterministic Muller automaton was given by McNaughton [12]. The construction we presented in section 4.4 is due to Safra [20]. Finally, the coalgebraic perspective on stream automata presented in the final section of this chapter is the author's.

#### Exercises

**Exercise 4.1** Provide Büchi automata recognizing exactly the following stream languages:

- (a)  $L_a = \{ \alpha \in \{a, b, c\}^{\omega} \mid a \text{ and } b \text{ occur infinitely often in } \alpha \}$
- (b)  $L_b = \{ \alpha \in \{a, b, c\}^{\omega} \mid \text{any } a \text{ in } \alpha \text{ is eventually followed by a } b \}$
- (c)  $L_c = \{ \alpha \in \{a, b\}^{\omega} \mid \text{between any two } a$ 's is an even number of b's  $\}$
- (d)  $L_d = \{ \alpha \in \{a, b, c\}^{\omega} \mid ab \text{ and } cc \text{ occur infinitely often in } \alpha \}$

**Exercise 4.2** Let C be a finite set. Show that the class of  $\omega$ -regular languages over C is closed under the Boolean operations, i.e., show that

- (a) If  $L \subseteq C^{\omega}$  is  $\omega$ -regular then its complement  $\overline{L} := \{\gamma \in C^{\omega} \mid \gamma \notin L\}$  is  $\omega$ -regular.
- (b) If  $L_1$  and  $L_2$  are  $\omega$ -regular C-stream languages, then  $L_1 \cup L_2$  is  $\omega$ -regular.
- (c) If  $L_1$  and  $L_2$  are  $\omega$ -regular C-stream languages, then  $L_1 \cap L_2$  is  $\omega$ -regular.

**Exercise 4.3** Observe that Büchi automata can also be seen as finite automata operating on *finite* words (see Example 4.9.

(a) Show the following, for any deterministic Büchi automaton A:

 $L_{\omega}(\mathbb{A}) = \{ \alpha \in \Sigma^{\omega} \mid \text{infinitely many prefixes of } \alpha \text{ belong to } L(\mathbb{A}) \}.$ 

(b) Does this hold for nondeterministic Büchi automata as well?

**Exercise 4.4** Let C and D be finite sets and let  $f: C \to D$  be a function. The function f can be extended to a function  $\overline{f}: C^{\omega} \to D^{\omega}$  in the obvious way by putting  $\overline{f}(\gamma) := f(c_0)f(c_1)f(c_2)\ldots \in D^{\omega}$  for any C-stream  $\gamma \in C^{\omega}$ . For a given C-stream language  $L \subseteq C^{\omega}$  we define

$$\overline{f}(L) := \{\overline{f}(\gamma) \mid \gamma \in L\} \subseteq D^{\omega}.$$

- (a) Show that  $L \subseteq C^{\omega}$  is  $\omega$ -regular implies  $f(L) \subseteq D^{\omega}$  is  $\omega$ -regular.
- (b) Show that there is a C-stream language  $L \subseteq C^{\omega}$  such that  $L = L_{\omega}(\mathbb{A})$  for some *de*terministic Büchi automaton  $\mathbb{A}$  and such that  $f(L) \subseteq D^{\omega}$  is not recognizable by any deterministic Büchi automaton.

**Exercise 4.5** Prove that nondeterministic Büchi automata have the same recognizing power as their Muller variants by showing that the automata  $\mathbb{A}'$  and  $\mathbb{A}$  in the proof of Proposition 4.24 are indeed equivalent.

**Exercise 4.6** Consider the language  $L_d$  of exercise 4.1.

- (a) Give a clear description of the complement  $\overline{L_d}$  of  $L_d$ .
- (b) Give a nondeterministic Büchi automaton recognizing exactly the language  $\overline{L_d}$ .
- (c) Prove that there is no deterministic Büchi automaton recognizing the language  $\overline{L_d}$ . (Hint: use the theorem from Exercise 4.3.)

**Exercise 4.7** Provide deterministic Muller automata recognizing the following languages:

- (a)  $L_d$  of exercise 4.1.
- (b)  $L_a = \{ \alpha \in \{a, b, c\}^{\omega} \mid \text{ between every pair of } a \text{'s is an occurrence of } bb \text{ or } cc \}.$

**Exercise 4.8 (regularity)** Let C be a finite set, and let  $L \subseteq C^{\omega}$  be a stream language over C. Prove that if L is  $\omega$ -regular, then it contains a stream of the form  $uv^{\omega}$  where  $u \in C^*$  and  $v \in C^+$ .

**Exercise 4.9** Describe the languages that are recognized by the following Muller automata (presented in tabular form, with  $\Rightarrow$  indicating the initial state):

(a) 
$$\begin{array}{c|c|c|c|c|c|c|c|c|} \hline \mathbb{A} & a & b \\ \hline \Rightarrow & q_0 & q_1 & q_2 \\ \hline & q_1 & q_0 & q_2 \\ \hline & q_2 & q_1 & q_0 \end{array}$$
 with  $\mathcal{F} := \{\{q_0, q_1\}, \{q_0, q_2\}\}.$ 

(b) The same automaton as in (a) but with  $\mathcal{F} := \{\{q_1, q_2\}, \{q_0, q_1, q_2\}\}$ .

	A		a	b	с		
	$\Rightarrow$	$q_0$	$q_1$	$q_0$	$q_0$		
(c)		$q_1$	$q_0$	$q_2$	$q_0$	with	$\mathcal{F} := \{\{q_0\}, \{q_0, q_1\}, \{q_0, q_1, q_2\}\}.$
		$q_2$	$q_0$	$q_0$	$q_3$		
		$q_3$	$q_0$	$q_0$	$q_0$		

**Exercise 4.10** Prove (47) in the proof of Proposition 4.35. That is, show that

for all i > 0 and for all  $a \in A_{i+1}$  there is an  $a' \in A_i$  such that  $a' \xrightarrow{\gamma[k_i, k_{i+1})}{\twoheadrightarrow_F} a$ .

Can you also prove that, conversely,

for all i > 0 and for all  $a \in A_i$  there is an  $a' \in A_{i+1}$  such that  $a' \xrightarrow{\gamma[k_i, k_{i+1})}{\twoheadrightarrow_F} a$ ?

## 5 Parity games

A large part of the theory of modal fixpoint logic involves nontrivial concepts and results from the theory of infinite games. In this chapter we discuss some of the highlights of this theory in a fair amount of detail. This allows us to be rather informal about game-theoretic concepts in the rest of the notes.

### 5.1 Board games

The games that we are dealing with here can be classified as *board* or *graph games*. They are played by two agents, here to be called 0 and 1.

**Definition 5.1** If  $\sigma \in \{0, 1\}$  is a player, then  $\overline{\sigma}$  denotes the *opponent*  $1 - \sigma$  of  $\sigma$ .

A board game is played on a *board* or *arena*, which is nothing but a directed graph. A *match* or *play* of the game consists of the two players moving a token across the board, following the edges of the graph. To regulate this, the collection of graph nodes, usually referred to as *positions* of the game, is partitioned into two sets, one for each player. Thus with each position we may associate a unique *owner*: the player whose turn it is to move when the token lies on this position.

**Definition 5.2** A board or arena is a structure  $\mathbb{B} = \langle B_0, B_1, E \rangle$ , such that  $B_0$  and  $B_1$  are disjoint sets, and  $E \subseteq B^2$ , where  $B := B_0 \cup B_1$ . We will make use of the notation E[p] for the set of admissible or legitimate moves from a board position  $p \in B$ , that is,  $E[p] := \{q \in B \mid (p,q) \in E\}$ . Positions not in E[p] will sometimes be referred to as illegitimate moves with respect to p. A position  $p \in B$  is a dead end if  $E[p] = \emptyset$ . If  $p \in B$ , we let  $\sigma_p$  denote the (unique) player such that  $p \in B_{\sigma_p}$ , and say that p belongs to  $\sigma_p$ , or that it is  $\sigma_p$ 's turn to move at p.

**Remark 5.3** Occasionally it will be convenient to represent a board in an alternative yet equivalent manner, viz., as a triple  $\mathbb{B} = \langle B, E, \sigma \rangle$  such that (B, E) is a graph and  $\sigma : B \to \{0, 1\}$  is a map assigning a player to each position in B. It is obvious how to switch from one presentation to another.

A match of the game may in fact be identified with the sequence of positions visited during play, and thus corresponds to a *path* through the graph. We refer to the Appendix A for some notation concerning paths.

**Definition 5.4** A path through a board  $\mathbb{B} = \langle B_0, B_1, E \rangle$  is a nonempty (finite or infinite) sequence  $\pi \in B^{\infty}$  such that  $E\pi_i\pi_{i+1}$  whenever applicable. A full or complete match or play through  $\mathbb{B}$  is either an infinite  $\mathbb{B}$ -path, or a finite  $\mathbb{B}$ -path  $\pi$  ending with a dead end (i.e.  $E[\mathsf{last}(\pi)] = \emptyset$ ).

A partial match is a finite path through  $\mathbb{B}$  that is not a full match; in other words, the last position of a partial match is not a dead end. We let PM denote the set of all partial matches, and  $PM_{\sigma}$  the set of partial matches such that  $\sigma$  is the player whose turn it is to move at the last position of the match. In the sequel, we will denote this player as  $\sigma_{\pi}$ ; that is,  $\sigma_{\pi} := \sigma_{\mathsf{last}(\pi)}$ .

Each full or completed match is *won* by one of the players, and *lost* by their opponent; that is, there are no draws. A finite match ends if one of the players gets *stuck*, that is, is forced to move the token from a position without successors. Such a finite, completed, match is lost by the player who got stuck.

If neither player ever gets stuck, an infinite match arises. The flavor of a board game is very much determined by the winning conditions of these infinite matches.

**Definition 5.5** Given a board  $\mathbb{B}$ , a winning condition is a map  $W : B^{\omega} \to \{0, 1\}$ . An infinite match  $\pi$  is won by  $W(\pi)$ . A board game is a structure  $\mathcal{B} = \langle B_0, B_1, E, W \rangle$  such that  $\langle B_0, B_1, E \rangle$  is a board, and W is a winning condition on B.

Although the winning condition given above applies to all infinite *B*-sequences, it will only make sense when applied to matches. We have chosen the above definition because it is usually much easier to formulate maps that are defined on all sequences.

Before players can actually start playing a game, they need a starting position. The following definition introduces some terminology and notation.

**Definition 5.6** An *initialized board game* is a pair consisting of a board game  $\mathcal{B}$  and a position q on the board of  $\mathcal{B}$ ; such a pair is usually denoted  $\mathcal{B}@q$ .

Given a (partial) match  $\pi$ , its first element first( $\pi$ ) is called the *starting position* of the match. We let  $\text{PM}_{\sigma}(q)$  denote the set of partial matches for  $\sigma$  that start at position q.

It is sometimes convenient to represent an (initialised) game by its game tree.

**Remark 5.7** Let q be a position in a board game  $\mathcal{B} = (B_0, B_1, E, W)$ . The game tree of  $\mathcal{B}$  at q is given as the tree  $\mathbb{T}_q^{\mathcal{B}} := (\mathrm{PM}(q), \vec{E}, q)$ , where  $\vec{E}$  is the relation

$$\vec{E} := \{ (\pi, \pi \cdot p) \mid p \in E[\mathsf{last}(\pi)] \},\$$

and q is the one-node match starting and ending at q. That is,  $\mathbb{T}_q^{\mathcal{B}}$  is the unravelling of the frame (B, E) around q. Clearly, full matches of  $\mathcal{B}@q$  correspond to branches of  $\mathbb{T}_q^{\mathcal{B}}$ , with finite matches corresponding to childless nodes, and infinite matches to infinite branches.

One may think of  $\mathbb{T}_q^{\mathcal{B}}$  itself as a board game  $\mathcal{B}_q^T$  by partitioning its nodes in the obvious way:  $\mathrm{PM}(q) = \mathrm{PM}_0(q) \uplus \mathrm{PM}_1(q)$ , and formulating the obvious winning conditions. We will usually confine our attention to the version of this game that is initialised at the root q.

Central in the theory of games is the notion of a *strategy*. Roughly, a strategy for a player is a method that the player uses to decide how to continue partial matches when it is their turn to move. More precisely, a strategy is a function mapping partial plays for the player to new positions. It is a matter of definition whether one requires a strategy to always assign moves that are legitimate, or not; here we will not make this requirement. For the following definition, recall that  $\Box$  denotes the initial segment relation on sequences (and thus, on matches).

Lectures on the modal  $\mu$ -calculus

**Definition 5.8** Given a board game  $\mathcal{B} = \langle B_0, B_1, E, W \rangle$  and a player  $\sigma$ , a  $\sigma$ -strategy, or a strategy for  $\sigma$ , is a map  $f : \mathrm{PM}_{\sigma} \to B$ . In case we are dealing with an initialized game  $\mathcal{B}@q$ , then we may take a strategy to be a map  $f : \mathrm{PM}_{\sigma}(q) \to B$ . A match  $\pi$  is consistent with or guided by a  $\sigma$ -strategy f if for any partial match  $\pi' \sqsubset \pi$  with  $\mathsf{last}(\pi') \in B_{\sigma}$ , the next position on  $\pi$  (after  $\pi'$ ) is indeed the element  $f(\pi')$ .

A  $\sigma$ -strategy f is surviving in  $\mathcal{B}@q$  if the moves that it prescribes to f-guided partial matches in  $\mathrm{PM}_{\sigma}@q$  are always admissible to  $\sigma$ , and winning for  $\sigma$  in  $\mathcal{B}@q$  if in addition all f-guided full matches starting at q are won by  $\sigma$ . A position  $q \in B$  is winning for  $\sigma$  if  $\sigma$  has a winning strategy for the game  $\mathcal{B}@q$ ; the collection of all winning positions for  $\sigma$  in  $\mathcal{B}$  is called the winning region for  $\sigma$  in  $\mathcal{B}$ , and denoted as  $\mathrm{Win}_{\sigma}(\mathcal{B})$ .

Intuitively, f being a surviving strategy in  $\mathcal{B}@q$  means that  $\sigma$  never gets stuck in an f-guided match of  $\mathcal{B}@q$ , and so guarantees that  $\sigma$  can stay in the game forever.

**Remark 5.9** Where f is a surviving for player  $\sigma$  in  $\mathcal{B}@a$ , we may *represent* f as the pruned subtree of the game tree  $\mathbb{T}_a^{\mathcal{B}}$  that is based on those nodes that correspond to f-guided matches of  $\mathcal{B}@a$ . In this so-called *strategy tree*  $\mathbb{T}_a^f$  we have

$$\vec{E}_f[\pi] := \begin{cases} \vec{E}[\pi] & \text{if } \pi \in \mathrm{PM}_{\overline{\sigma}} \\ \{\pi \cdot f(\pi)\} & \text{if } \pi \in \mathrm{PM}_{\sigma} \end{cases}$$

for any node  $\pi \in PM(a)$ .

**Convention 5.10** Observe that we allow strategies that prescribe illegitimate moves. In practice, it will often be convenient to extend the definition of a strategy even further to include maps f that are *partial* in the sense that they are only defined on a proper subset of  $PM_{\sigma}$ . We will only permit ourselves such a sloppiness if we can guarantee that  $f(\pi)$  is defined for every  $\pi \in PM_{\sigma}$  that is consistent with the partial  $\sigma$ -strategy f, so that the situation where the partial strategy actually would fail to suggest a move, will never occur.

It is easy to see that a position in a game  $\mathcal{B}$  cannot be winning for *both* players. On the other hand, the question whether a position p is always a winning position for *one* of the players, is a rather subtle one. Observe that in such games the two winning regions *partition* the game board.

**Definition 5.11** The game  $\mathcal{B}$  on the board  $\mathbb{B}$  is determined if  $\operatorname{Win}_0(\mathcal{B}) \cup \operatorname{Win}_1(\mathcal{B}) = B$ ; that is, each position is winning for one of the players.

It turns out that the axiom of choice implies the existence of infinite games that admit positions from which neither player has a winning strategy.

▶ Add some more detail, including a remark on the axiom of determinacy in set theory.

In principle, when deciding how to move in a match of a board game, players may use information about the entire history of the match played thus far. However, it will turn out to be advantageous to work with strategies that are simple to compute. Particularly nice

 $\triangleleft$ 

are so-called *positional* strategies, which only depend on the current position (i.e., the final position of the partial play). Although their importance is sometimes overrated, positional strategies are convenient to work with, and they will be critically needed in the proofs of some of the most fundamental results in the automata-theoretic approach to fixpoint logic.

**Definition 5.12** A strategy f is *positional* or *history-free* if  $f(\pi) = f(\pi')$  for any  $\pi, \pi'$  with  $\mathsf{last}(\pi) = \mathsf{last}(\pi')$ .

**Convention 5.13** A positional  $\sigma$ -strategy may be represented as a map  $f: B_{\sigma} \to B$ .

As a slight generalisation of positional strategies, *finite-memory strategies* can be computed using only a finite amount of information about the history of the match. More details can be found in Exercise 5.2.

Before finishing this section we note that any set of positions on a board naturally induces a subboard, based on the restricted edge relation, and similarly for games.

**Definition 5.14** Given a board  $\mathbb{B} = \langle B_0, B_1, E \rangle$ , a subset  $A \subseteq B$  determines the following subboard  $\mathbb{B}_A := \langle A \cap B_0, A \cap B_1, E_{\restriction A} \rangle$ , where  $E_{\restriction A} := E \cap (A \times A)$  is the restriction of E to A. Similarly, if  $W : B^{\omega} \to \{0, 1\}$  is a winning condition on  $\mathbb{B}$ , we let  $W_{\restriction A} : A^{\omega} \to \{0, 1\}$  denote the restriction of W to the set  $A^{\omega} \subseteq B^{\omega}$ , and with  $\mathcal{B} = \langle B_0, B_1, E, W \rangle$ , we define  $\mathcal{B}_A := \langle A \cap B_0, A \cap B_1, E_{\restriction A}, W_{\restriction A} \rangle$  as the subgame induced by A.

Note that, in the setting of this definition, a position  $b \in A$  may be a dead end in  $\mathbb{B}_A$  but not in  $\mathbb{B}$ . More in general, a winning strategy for one of the players in  $\mathbb{B}_A@b$  is not necessarily a winning strategy for this player in  $\mathbb{B}@b$ .

### 5.2 Winning conditions

In case we are dealing with a *finite* board B, then we may nicely formulate winning conditions in terms of the set of positions that occur *infinitely often* in a given match. But in the case of an infinite board, there may be matches in which no position occurs infinitely often (or more than once, for that matter). Nevertheless, we may still define winning conditions in terms of objects that occur infinitely often, if we make use of *finite colorings* of the board. If we assign to each position  $b \in B$  a *color*, taken from a finite set C of colors, then we may formulate winning conditions in terms of the infinite *color sequence* induced by an infinite match.

**Definition 5.15** A coloring of B is a function  $\Gamma: B \to C$  assigning to each position  $p \in B$ a color  $\Gamma(p)$  taken from some finite set C of colors. By putting  $\Gamma(p_0p_1\cdots) := \Gamma(p_0)\Gamma(p_1)\cdots$ we can naturally extend such a coloring  $\Gamma: B \to C$  to a map  $\Gamma: B^{\omega} \to C^{\omega}$ .

Now if  $\Gamma : B \to C$  is a coloring, for any infinite sequence  $\pi \in B^{\omega}$ , the map  $\Gamma \circ \pi \in C^{\omega}$  forms the associated sequence of colors. Most if not all interesting types of graph games have winning conditions that can be expressed in terms of this induced sequence. An interesting example is given by the so-called *regular games*, that is, board games where the winning condition is given as an  $\omega$ -regular language over some colouring of the board.

Lectures on the modal  $\mu$ -calculus

**Definition 5.16** An infinite game  $\mathcal{B} = \langle B_0, B_1, E, W \rangle$  is called  $(\omega$ -)regular if there exists an  $\omega$ -regular language L over some finite alphabet C and a colouring  $\Gamma : B \to C$ , such that player 0 wins a match  $\pi = (p_i)_{i < \omega} \in B^{\omega}$  precisely if the induced sequence  $(\Gamma(p_i))_{i < \omega} \in C^{\omega}$ belongs to L.

In Exercise 5.2 the reader is asked to prove that these regular games are determined, and that we may assume that the winning strategies of each player in a regular game are finite-memory strategies.

A special kind of regular game is given by the Muller game. Here, the definition of the winning condition is based on the observation that if an infinite game has an associated colouring, then for any infinite match there must be a nonempty set of colours that occur infinitely often in this stream.

**Definition 5.17** Let  $\mathbb{B}$  be a board and  $\Gamma: B \to C$  a coloring of B. Given an infinite sequence  $\pi \in B^{\omega}$ , we let  $Inf_{\Gamma}(\pi)$  denote the set of colors that occur infinitely often in the sequence  $\Gamma \circ \pi$ .

A Muller condition is a collection  $\mathcal{M} \subseteq \wp(C)$  of subsets of C. The corresponding winning condition is defined as the following map  $W_{\mathcal{M}} : B^{\omega} \to \{0, 1\}$ :

$$W_{\mathcal{M}}(\pi) := \begin{cases} 0 & \text{if } Inf_{\Gamma}(\pi) \in \mathcal{M} \\ 1 & \text{otherwise.} \end{cases}$$

A *Muller game* is a board game of which the winning conditions are specified by a Muller condition.  $\triangleleft$ 

In words, player 0 wins an infinite match  $\pi = p_0 p_1 \cdots$  if the set of colors one meets infinitely often on this path, belongs to the Muller collection  $\mathcal{M}$ . It is not difficult to see that Muller games can be presented as regular games, and thus inherit the properties of determinacy and the existence of winning strategies that require only a finite amount of memory.

These results becomes even nicer if the Muller condition allows a formulation in terms of a priority map. In this case, as colors we take natural numbers. Note that by definition of a coloring, the range  $\Omega[B]$  of the coloring function  $\Omega$  is finite. This means that every nonempty subset of  $\Omega[B]$  has a maximal element. Hence, every match determines a unique natural number, namely, the 'maximal color' that one meets infinitely often during the match. Now the parity winning condition states that the winner of an infinite match is 0 if this number is even, and 1 if it is odd. More succinctly, we formulate the following definition.

**Definition 5.18** Let *B* be some set; a *priority map* on *B* is a coloring  $\Omega : B \to \omega$ , that is, a map of finite range. A *parity game* is a board game  $\mathcal{B} = \langle B_0, B_1, E, W_{\Omega} \rangle$  in which the winning condition is given by

$$W_{\Omega}(\pi) := \max(Inf_{\Omega}(\pi)) \mod 2.$$

Such a parity game is usually denoted as  $\mathcal{B} = \langle B_0, B_1, E, \Omega \rangle$ .

 $\triangleleft$ 

#### ▶ Many examples

As a variation of the above parity game, we sometimes consider a version where the priority map is only partial.

**Definition 5.19** Let  $\mathbb{B} = (B, E, \sigma)$  be a board. A partial priority map  $\Omega$  for  $\mathbb{B}$  is a partial map  $\Omega : B \xrightarrow{\circ} \omega$  such that  $\Omega[B]$  is finite and  $\mathsf{Dom}(\Omega)$  is cycle-critical in  $\mathbb{B}$ , that is, every cycle in  $\mathbb{B}$  contains at least one position in  $\mathsf{Dom}(\Omega)$ . To define the winning conditions for these games, we observe that the set  $Inf_{\Omega}(\pi)$  is non-empty, for any infinite match  $\pi$ , so that we may define

$$W_{\Omega}(\pi) := \max(Inf_{\Omega}(\pi)) \mod 2,$$

just as in the case of a total priority map, A *ppm-parity game* is a game of the form  $(B_0, B_1, E, W_{\omega})$ , where W is induced by a partial priority map  $\Omega$  for  $\mathbb{B}$ .

Obviously, any standard parity game corresponds to a ppm-parity game where the priority map is total. Conversely, it is straightforward to transform a ppm-parity game into a standard parity game — we leave the details for the reader.

The key property that makes parity games so interesting and nice to work with is that they enjoy positional determinacy, as we will prove in section 5.4. First, however, we turn to the special case of so-called reachability games.

#### 5.3 Reachability games and attractor sets

Reachability games are a special kind of board games. They are played on a board such as described in section 5.1, but also feature a special set of positions. The aim of the game is for one player to move the token into this special set and for the other to avoid this to happen.

**Definition 5.20** Fix a board  $\mathbb{B}$  and a subset  $A \subseteq B$ . The reachability game  $\mathcal{R}_{\sigma}(\mathbb{B}, A)$  is defined as the game over  $\mathbb{B}$  in which  $\sigma$  wins as soon as a position in A is reached or if  $\overline{\sigma}$  gets stuck. On the other hand,  $\overline{\sigma}$  wins if he can manage to keep the token outside of A infinitely long, or if  $\sigma$  gets stuck.

As an example, if  $A = \emptyset$ , in order to win the game  $\mathcal{R}_{\sigma}(\mathbb{B}, A)$  for player  $\overline{\sigma}$  it simply suffices to stay alive forever, while  $\sigma$  can only win by forcing  $\overline{\sigma}$  to get stuck.

**Remark 5.21** If we want reachability games to fit the format of a board game exactly, we have to modify the board, as follows. Given a reachability game  $\mathcal{R}_{\sigma}(\mathbb{B}, A)$ , define the board  $\mathbb{B}' := \langle B'_0, B'_1, E' \rangle$  by putting:

$$\begin{array}{rcl} B'_{\sigma} & := & B_{\sigma} \setminus A \\ B'_{\overline{\sigma}} & := & B_{\overline{\sigma}} \cup A \\ E' & := & \{(p,q) \in E \mid p \notin A\}. \end{array}$$

In other words,  $\mathbb{B}'$  is like  $\mathbb{B}$  except that all positions in A are now dead ends, assigned to player  $\overline{\sigma}$ . This means that  $\overline{\sigma}$  gets stuck in a position belonging to A. Furthermore, the winning conditions of such a game are very simple: simply define  $W : B^{\omega} \to \{0, 1\}$  as the constant function mapping all infinite matches to  $\overline{\sigma}$ . This can easily be formulated as a parity condition. Since reachability games can thus be formulated as very simple parity games, the following theorem, stating that reachability games enjoy positional determinacy, can be seen as a warming up exercise for the general case. Alternatively, reachability can be seen as an *unfolding game* for some monotone functional over the power set of the board, so that its positional determinacy follows from  $\overline{X}$ . We leave the proof details as an exercise for the reader.

**Theorem 5.22 (Positional determinacy of reachability games)** Let  $\mathcal{R}$  be a reachability game. Then there are positional strategies  $f_0$  and  $f_1$  for 0 and 1, respectively, such that for every position q there is a player  $\sigma$  such that  $f_{\sigma}$  is a winning strategy for  $\sigma$  in  $\mathcal{R}@q$ .

**Definition 5.23** The winning region for  $\sigma$  in  $\mathcal{R}_{\sigma}(\mathbb{B}, A)$  is called the *attractor set* of  $\sigma$  for A in  $\mathbb{B}$ , notation:  $Attr_{\sigma}^{\mathbb{B}}(A)$ . In the sequel we will fix a positional winning strategy for  $\sigma$  in  $\mathcal{R}_{\sigma}(\mathbb{B}, A)$  and denote it as  $attr_{\sigma}^{\mathbb{B}}(A)$ .

If no confusion arises, we will generally drop the superscript referring to the board, writing  $Attr_{\sigma}(A)$  and  $attr_{\sigma}(A)$  instead of  $Attr_{\sigma}^{\mathbb{B}}(A)$  and  $attr_{\sigma}^{\mathbb{B}}(A)$ . Note that  $\sigma$ -attractor sets always contain all points from which  $\sigma$  can make sure that  $\overline{\sigma}$  gets stuck. Furthermore, it is easy to see that in  $attr_{\sigma}(A)$ -guided matches the token never leaves  $Attr_{\sigma}(A)$  (at least if the match starts inside  $Attr_{\sigma}(A)$ !).

**Proposition 5.24** Let  $\mathbb{B}$  be some board. Then  $Attr_{\sigma}^{\mathbb{B}}$  is a closure operation on  $\wp(B)$ , i.e.

- 1.  $A \subseteq A'$  implies  $Attr^{\mathbb{B}}_{\sigma}(A) \subseteq Attr^{\mathbb{B}}_{\sigma}(A')$ ,
- 2.  $A \subseteq Attr^{\mathbb{B}}_{\sigma}(A)$ ,
- 3.  $Attr^{\mathbb{B}}_{\sigma}(Attr^{\mathbb{B}}_{\sigma}(A)) = Attr^{\mathbb{B}}_{\sigma}(A).$

**Proof.** For part 1, simply observe that any strategy for  $\sigma$  that forces the token eventually to A, at the same time forces the token into A'. Part 2 is immediate by the definitions.

For part 3, we only need to prove the inclusion  $\subseteq$ , since the opposite inclusion follows from part 2. Take some arbitrary position  $b \in Attr^{\mathbb{B}}_{\sigma}(Attr^{\mathbb{B}}_{\sigma}(A))$ . That is,  $\sigma$  has some strategy f that is guaranteed to eventually lead the token into  $Attr^{\mathbb{B}}_{\sigma}(A)$ . Suppose then that  $\sigma$  uses this strategy, and as soon as the match has arrived to  $Attr^{\mathbb{B}}_{\sigma}(A)$ , she switches to the attractor strategy for A. It should be obvious that this is a winning strategy in the reachability game of A, starting from a. QED

A kind of counterpart to attractor sets are *closed sets*. In words, a set A is  $\sigma$ -closed if  $\sigma$  has the power to keep the token inside A while not getting stuck.

**Definition 5.25** Given a board  $\mathbb{B}$ , we call a subset  $A \subseteq B \sigma$ -closed (or a  $\overline{\sigma}$ -trap) if  $E[b] \subseteq A$  for all  $b \in A \cap B_{\overline{\sigma}}$ , while  $E[b] \cap A \neq \emptyset$  for all  $b \in A \cap B_{\sigma}$ .

Note that a  $\sigma$ -closed set does not contain  $\sigma$ -endpoints and that  $\sigma$  will therefore never get stuck in a  $\sigma$ -closed set. We conclude this section with a useful proposition.

**Proposition 5.26** Let  $\mathbb{B}$  be a board and  $A \subseteq B$  an arbitrary subset of B. Then the following assertions hold.

- 1. If A is  $\sigma$ -closed then so is  $Attr_{\sigma}^{\mathbb{B}}(A)$ .
- 2. The complement of  $Attr^{\mathbb{B}}_{\sigma}(A)$  is  $\overline{\sigma}$ -closed.
- 3. The union  $\bigcup \{A_i \mid i \in I\}$  of an arbitrary collection of  $\sigma$ -closed sets is again  $\sigma$ -closed.
- 4. If A is  $\sigma$ -closed in  $\mathbb{B}$  then any  $C \subseteq A$  is  $\sigma$ -closed in  $\mathbb{B}$  iff C is  $\sigma$ -closed in  $\mathbb{B}_A$ .
- 5. If  $C \subseteq B$  is  $\sigma$ -closed, then  $Attr_{\sigma}^{\mathbb{B}_C}(A \cap C) \subseteq Attr_{\sigma}^{\mathbb{B}}(A) \cap C$ .

**Proof.** All statements are easily verified and thus the proof is left to the reader. QED

Lectures on the modal  $\mu$ -calculus

#### 5.4 Positional Determinacy of Parity Games

Probably the most attractive property of parity games is that we may always assume that players have a *positional* winning strategy starting from any of their winning positions.

**Definition 5.27** A board game  $\mathcal{B} = \langle B_0, B_1, E, W \rangle$  enjoys positional determinacy if  $B = Win_0(\mathcal{B}) \cup Win_1(\mathcal{B})$ , and there are positional strategies  $f_0$  and  $f_1$  such that for each player  $\sigma$  and every  $b \in Win_{\sigma}(\mathcal{B})$ , the strategy  $f_{\sigma}$  is winning for  $\sigma$  in  $\mathcal{B}@b$ .

**Theorem 5.28 (Positional Determinacy of Parity Games)** Let  $\mathcal{B}$  be a parity game. Then  $\mathcal{B}$  enjoys positional determinacy.

Related to positional determinacy, and an important tool in the proof of Theorem 5.28 is the notion of a player's *paradise*. In words, a subset  $A \subseteq B$  is a  $\sigma$ -paradise if  $\sigma$  has a positional strategy f which guarantees, for any position  $a \in A$ , both that she wins the game  $\mathcal{B}@a$ , and that the token stays in A. Thus in particular, a  $\sigma$ -paradise is  $\sigma$ -closed.

**Definition 5.29** Given a board game  $\mathcal{B}$ , we call a  $\sigma$ -closed set A a  $\sigma$ -paradise if there exists a positional winning strategy  $f : A \cap B_{\sigma} \to A$ .

The importance of this notion is clear from the following proposition. We omit its proof since it is straightforward.

**Proposition 5.30** Let  $\mathcal{B}$  be some board game. Then  $\mathcal{B}$  enjoys positional determinacy iff its board can be partitioned into a 0-paradise and a 1-paradise.

The remainder of this section is organized as follows. We first give a straightforward proof the positional determinacy of parity games in the finite case. In the next subsection we discuss the notion of a paradise in more detail, and in the final subsection we apply our findings to prove Theorem 5.28 in the general setting.

#### 5.4.1 Positional determinacy of parity games: the finite case

In the case where  $\mathcal{B}$  is based on a *finite board*, we can give a relatively straightforward proof of positional determinacy.

**Proposition 5.31** Let  $\mathcal{B}$  be a finite parity game. Then its board can be partitioned into a 0-paradise and a 1-paradise.

**Proof.** Let  $\mathbb{B} = (B_0, B_1, E)$  be the board of  $\mathcal{B}$ , and let  $\Omega$  be its priority map. We will prove this proposition by induction on d, the maximal parity in the game (i.e.  $d := \max(\Omega[B])$ ). If d = 0 we are dealing with a reachability game (namely  $\mathcal{R}_1(\mathbb{B}, \emptyset)$ ), and so the result follows by Theorem 5.22.

We thus focus on the inductive case, where  $d \ge 1$ . Without loss of generality we may assume that d is even — in the case where d is odd we proceed in a similar way. The key observation in the finite case is that we may use an inner induction on the size  $|\mathcal{B}|$  of  $\mathcal{B}$ , that is, the number of its positions. Define  $M := \{b \in X \mid \Omega(b) = d\}$  to be the set of all positions in  $\mathcal{B}$  that actually reach the maximum priority d and let  $M^+ := Attr_0^{\mathbb{B}}(M)$  be its attractor set. Note that M, and hence also  $M^+$ , must be nonempty.

We may apply the (outer or inner) inductive hypothesis to the subgame  $\mathcal{H}$  of  $\mathcal{B}$  that is based on the set  $B \setminus M^+$ . Let  $A_0$  and  $A_1$ , respectively, be the winning regions for the two players of  $\mathcal{H}$ , with positional winning strategies, respectively,  $g_0$  and  $g_1$ . Furthermore, let  $A_1^+ := Attr_0^{\mathbb{B}}(M)$  be the attractor set of  $A_1$  (with respect to the full board  $\mathbb{B}$ ). Note that whereas  $A_1$  must be disjoint from  $M^+$ , the set  $A_1^+$  may overlap with  $M^+$ , and even with M.

We now make a case distinction as to whether  $A_1^+$  is empty or not.

Case  $A_1^+ \neq \emptyset$ . In this case we may apply the (inner) induction hypothesis to the subgame  $\mathcal{B}^-$  of  $\mathcal{B}$  that is based on the complement  $B \setminus A_1^+$  of  $A_1^+$ . This gives us a partition of the board of  $\mathcal{B}^-$  into winning regions  $W_0^-$  and  $W_1^-$ , together with positional winning strategies  $f_0^-$  and  $f_1^-$  such that for every position  $b \in W_{\sigma}^-$ , the strategy  $f_{\sigma}$  is winning for  $\sigma$  in  $\mathcal{B}^-$ @b.

CLAIM 1 1)  $W_0 := W_0^-$  is a 0-paradise in  $\mathcal{B}$ , with positional winning strategy  $f_0^-$ ; 2)  $W_1 := W_1^- \cup A_1^+$  is a 1-paradise in  $\mathcal{B}$ , with positional winning strategy  $f_1$  given by:

$$f_1(b) := \begin{cases} g_1(b) & \text{if } b \in A_1 \\ attr_1^{\mathbb{B}}(A_1)(b) & \text{if } b \in A_1^+ \setminus A_1 \\ f_1^-(b) & \text{if } b \in W_1^-. \end{cases}$$

PROOF OF CLAIM We leave the verification of part (1) as an exercise for the reader. For the second part, consider an arbitrary  $f_1$ -guided match  $\pi$  starting from some position  $b \in W^1$ . If  $b \in A_1$ , it should be clear that  $\pi$  stays in  $A_1$ : player 1 will keep the token there, while player 0 cannot leave  $A_1$  since it is 1-closed. It follows that  $\pi$  is a  $g_1$ -guided  $\mathcal{H}$ -match; it is thus won by 1 in  $\mathcal{H}$ , and hence, also in  $\mathcal{B}$ . It is then easy to see that  $f_1$ is also winning when the match starts at some  $b \in A_1^+ \setminus A_1$  — we leave the details for the reader.

Finally then, if  $b \in W_1^-$ , then it is not hard to show that  $\pi$  will stay in  $W_1^-$ , unless player 0 manages to move the token out of there. However, player 0 will not be able to move the token to a position in  $W_0^-$  — if so, the position from which this were possible would itself belong to  $W_0^-$ . The only way out for player 0, then, is to move the token to a position in  $A_1^+$ ; but if she does so then her opponent simply switches to the positional winning strategy described in the above paragraph. Hence every match that leaves  $W_1^$ is won by player 1. But if the match stays in  $W_1^-$ , it is clearly a win for him as well.

Case  $A_1^+ = \emptyset$ . Clearly this implies that also  $A_1 = \emptyset$ , and that  $E[b] \neq \emptyset$ , for any position  $b \in B_0$ . We may thus pick an element  $k(b) \in E[b]$ , for any  $b \in B_0$ . Furthermore,  $A_1$  being empty implies that every position in  $B \setminus M^+$  is winning for 0 in  $\mathcal{H}$ . This means in particular, that  $g_0(b)$  is defined for every  $b \in B_0 \setminus M^+$ . We now claim that every

position in  $\mathcal{B}$  is winning for player 0, and that she may use the positional strategy  $f_0$ , which is defined by putting, for  $b \in B_0$ :

$$f_0(b) := \begin{cases} k(b) & \text{if } b \in M \\ attr_1^{\mathbb{B}}(M)(b) & \text{if } b \in M^+ \setminus M \\ g_0(b) & \text{if } b \in B \setminus M^+. \end{cases}$$

We leave the proof of this claim as an exercise for the reader.

QED

#### 5.4.2 Paradises

As mentioned, the proof of positional determinacy for parity games in the general case is slightly more involved. We need the following proposition which establishes some basic facts about paradises. In this section we also provide some further observations about paradises that will be of use when we discuss algorithms for solving parity games in section 5.5.

**Proposition 5.32** Let  $\mathcal{B}(\mathbb{B},\Omega)$  be a parity game. Then the following hold:

- 1. The union  $\bigcup \{P_i \mid i \in I\}$  of an arbitrary set of  $\sigma$ -paradises is again a  $\sigma$ -paradise.
- 2. There exists a largest  $\sigma$ -paradise.
- 3. If P is a  $\sigma$ -paradise then so is  $Attr_{\sigma}(P)$ .

**Proof.** The main point of the proof of part (1) is that we somehow have to uniformly choose a strategy on the intersection of paradises, such that we will end up following the strategy of only one paradise. For this purpose, we assume that we have a well-ordering on the index set I (i.e., for the infinite case we assume the Axiom of Choice).

For the details, assume that  $\{P_i \mid i \in I\}$  is a family of paradises, and let  $f_i$  be the positional winning strategy for  $P_i$ . Note that  $P := \bigcup \{P_i \mid i \in I\}$  is  $\sigma$ -closed by Proposition 5.26. Assume that < is a well-ordering of I, so that for each  $q \in P$  there is a minimal index min(q) such that  $q \in P_{\min(q)}$ . Define a positional strategy on P by putting

$$f(q) := f_{\min(q)}(q).$$

This strategy ensures at all times that the token either stays in the current paradise, or else it moves to a paradise of lower index, and so, any match where  $\sigma$  plays according to f will proceed through a sequence of  $\sigma$ -paradises of decreasing index. Because of the well-ordering, this decreasing sequence of paradises cannot be strictly decreasing, and thus we know that after finitely many steps the token will remain in the paradise where it is, say,  $P_j$ . From that moment on, the match is continued as an  $f_j$ -guided match inside  $P_j$ , and since  $f_j$  is by assumption a winning strategy when played inside  $P_j$ , this match is won by  $\sigma$ .

Part (2) of the proposition should now be obvious: clearly the union of all  $\sigma$ -paradises is the greatest  $\sigma$ -paradise.

In order to prove part (3) we need to show that there exists a positional winning strategy for  $\sigma$  starting from any position in  $Attr_{\sigma}(P)$ . The principal idea is to first move to P by  $attr_{\sigma}(P)$  and once there to follow the positional winning strategy in P. Let f' be the winning strategy for P, we then define the following strategy f on  $Attr_{\sigma}(P)$  by

$$f(p) := \begin{cases} f'(p) & \text{if } p \in P \\ attr_{\sigma}(P)(p) & \text{otherwise.} \end{cases}$$

A match consistent with this strategy will stay in  $Attr_{\sigma}(P)$  because this set is  $\sigma$ -closed and  $f(p) \in Attr_{\sigma}(P)$  for all  $p \in Attr_{\sigma}(P)$ . It is winning because if ever the match arrives at a point  $p \in P$  then play continues as if the match were completely in P; and since f' was supposed to be a winning strategy for  $\sigma$  this play is won by  $\sigma$ . If we start outside P we will at first follow the strategy  $attr_{\sigma}(P)$  which will ensure that  $\sigma$  either wins or that the token ends up in P, in which case  $\sigma$  will also win. QED

Below we list some properties of paradises that will become useful in the next section. The proof of the first proposition is left as a (fairly straightforward) exercise for the reader.

**Proposition 5.33** Let  $\mathcal{B} = (\mathbb{B}, \Omega)$  be a parity game, and let  $D \subseteq B$  be a  $\sigma$ -paradise, witnessed by a positional winning strategy f. Then the following hold:

- 1. Let  $C \subseteq B$  be  $\sigma$ -closed. If  $D \subseteq C$  then D is also a  $\sigma$ -paradise in  $\mathcal{B}_C$ .
- 2. If  $A \subseteq B$  is such that  $A \cap D = \emptyset$  then D is a  $\sigma$ -paradise in  $\mathcal{B}_X$ , where  $X := B \setminus Attr_{\overline{\sigma}}^{\mathbb{B}}(A)$ .
- 3. if  $A \subseteq B$  is  $\overline{\sigma}$ -closed then  $D \cap A$  is a  $\sigma$ -paradise in  $\mathcal{B}_A$ .

In each case, the statement is witnessed by the positional strategy f (restricted to the domain  $D \cap A$ , in the third item).

For the following proposition, recall that in a parity game  $\mathcal{B} = (B_0, B_1, E, \Omega), \ \Omega^{-1}[d]$  denotes the set of positions of priority d.

**Proposition 5.34** Let  $\mathcal{B} = (B_0, B_1, E, \Omega)$  be a parity game, and let  $D \subseteq B$  be a nonempty  $\sigma$ -paradise in  $\mathcal{B}$ . Write  $d := \max(\Omega[D])$ , and assume that  $\sigma$  is the opponent of  $d \mod 2$ . Then D has a nonempty subset  $C \subseteq D$  which is a  $\sigma$ -paradise, both in  $\mathcal{B}$  and in  $\mathcal{B}_D$ , and which does not overlap with  $Attr_{\overline{\sigma}}^{\mathbb{B}}(\Omega^{-1}[d])$ .

**Proof.** Let f be player  $\sigma$ 's positional winning strategy for D. Every f-guided  $\mathcal{B}$ -match  $\pi$  starting from some  $b \in D$  stays in D, and therefore, the set  $Occ(\Omega[\pi])$  of all priorities encountered during  $\pi$  satisfies max  $(Occ(\Omega[\pi])) \leq d$ . Define

 $C := \{ b \in D \mid \max\left( Occ(\Omega[\pi]) \right) < d \text{ for every } f \text{-guided match } \pi \text{ of } \mathcal{B}@b \},\$ 

that is, C consists of those position in D for which  $\sigma$  can guarantee that f-guided matches *never* pass a position of priority d (or higher).

Clearly then, C is a  $\sigma$ -paradise (both in  $\mathcal{B}$  and in  $\mathcal{B}_D$ ), witnessed by the strategy f (restricted to C). We also claim that C is nonempty, for otherwise there would be, for every

 $a \in D$ , a finite f-guided match  $\pi$ , starting at a and ending at a position  $a' \in D$  such that  $\Omega(a') = d$ . But then we may easily construct, starting from an arbitrary position in D, an f-guided match that passes a d-position *infinitely* often; this match would then be won by  $d \mod 2 = \overline{\sigma}$ , clearly contradicting our assumptions on f.

It remains to show that C does not overlap with the  $\overline{\sigma}$ -attractor set of  $\Omega^{-1}[d]$ , so assume for contradiction that  $a \in C \cap Attr_{\overline{\sigma}}^{\mathbb{B}}(\Omega^{-1}[d])$ . Now suppose that  $\sigma$  plays her strategy f against her opponent's attractor strategy, starting at this position a. The resulting match must reach a state in  $\Omega^{-1}[d]$ , but cannot leave D (with f being its paradise strategy). But then a cannot be an element of C, contradicting our assumption. QED

## 5.4.3 Positional determinacy of parity games: the general case

In this subsection we prove the positional determinacy of arbitrary (that is, not necessarily finite) parity games.

**Proposition 5.35** Let  $\mathcal{B}$  be a parity game. Then its board can be partitioned into a 0-paradise and a 1-paradise.

**Proof.** We will prove this proposition by induction on d, the maximal parity in the game (i.e.  $d = \max(\Omega[B])$ ). The base case of the induction is the same as in the finite case, so we move to the case where  $d \ge 1$ . Let  $\sigma := d \mod 2$ , that is,  $\sigma$  wins an infinite play  $\pi$  if  $\max(Inf(\pi)) = \max(\Omega[B]) = d$ . Let  $P_{\overline{\sigma}}$  be the maximal  $\overline{\sigma}$ -paradise, with associated positional strategy f. It now suffices to show that  $X := B \setminus P_{\overline{\sigma}}$  is a  $\sigma$ -paradise. This proof is depicted in Figure 3.

First we shall show that X is  $\sigma$ -closed. By proposition 5.32(3) it follows that  $Attr_{\overline{\sigma}}(P_{\overline{\sigma}})$  is itself also a  $\overline{\sigma}$ -paradise. By maximality of  $P_{\overline{\sigma}}$  and the fact that  $Attr_{\overline{\sigma}}$  is a closure operation, it follows that  $P_{\overline{\sigma}} = Attr_{\overline{\sigma}}(P_{\overline{\sigma}})$ . Thus by Proposition 5.26(2) we see that X, being the complement of a  $\overline{\sigma}$ -attractor set is  $\sigma$ -closed indeed.

Consider  $\mathcal{B}_X$ , the subgame of  $\mathcal{B}$  induced by X. Define  $M := \{b \in X \mid \Omega(b) = d\}$  to be the set of all points in X with priority d and let  $Z := X \setminus Attr_{\sigma}^{\mathbb{B}_X}(M)$ . Since Z is the complement of a  $\sigma$ -attractor set in  $\mathbb{B}_X$  it is  $\overline{\sigma}$ -closed in  $\mathbb{B}_X$ .

By the induction hypothesis we can split the subgame  $\mathcal{B}_Z$  into a 0-paradise  $Z_0$  and a 1-paradise  $Z_1$ , see the picture. The positional winning strategies in these paradises we call  $f_0$  and  $f_1$  respectively. (All notions are with regard to the game  $\mathcal{B}_Z$ .) We claim that

$$Z_{\overline{\sigma}} = \emptyset. \tag{51}$$

To prove this, we first show that  $P_{\overline{\sigma}} \cup Z_{\overline{\sigma}}$  is a  $\overline{\sigma}$ -paradise in  $\mathcal{B}$ . Consider the following strategy g for  $\overline{\sigma}$ :

$$g(b) := \begin{cases} f(b) & \text{if } b \in P_{\overline{\sigma}} \\ f_{\overline{\sigma}}(b) & \text{if } b \in Z_{\overline{\sigma}}. \end{cases}$$

It is left as an exercise for the reader to show that this is indeed a positional winning strategy for  $\overline{\sigma}$  in  $\mathcal{B}$ , which in addition keeps the token inside  $P_{\overline{\sigma}} \cup Z_{\overline{\sigma}}$ . By the definition of  $P_{\overline{\sigma}}$  as the maximal  $\overline{\sigma}$ -paradise, we see that  $P_{\overline{\sigma}} = P_{\overline{\sigma}} \cup Z_{\overline{\sigma}}$  and since  $P_{\overline{\sigma}}$  and  $Z_{\overline{\sigma}}$  are disjoint we conclude that  $Z_{\overline{\sigma}}$  must be empty indeed. This proves (51).

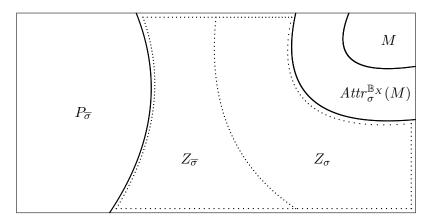

Figure 3: The proof of Proposition 5.35 in a picture

But from  $Z_{\overline{\sigma}} = \emptyset$  it immediately follows that  $Z = Z_{\sigma}$ , so that we find

$$X = Z_{\sigma} \cup Attr_{\sigma}^{\mathbb{B}_X}(M).$$

Recall that X is  $\sigma$ -closed, so that for each  $b \in X \cap B_{\sigma}$ , we may pick an arbitrary element  $k(b) \in E[b] \cap X$ . Now define the following strategy h in  $\mathcal{B}$  for  $\sigma$  on X.

$$h(b) := \begin{cases} k(b) & \text{if } b \in M \\ attr_{\sigma}(M)(b) & \text{if } b \in Attr_{\sigma}^{\mathbb{B}_{X}}(M) \setminus M \\ f_{\sigma}(b) & \text{if } b \in Z_{\sigma} = Z. \end{cases}$$

It is left as an exercise for the reader to show that h is indeed a winning strategy for  $\sigma$  in  $\mathcal{B}$ and that it keeps the token in X. QED

# 5.5 Algorithms for solving parity games

Solving a parity game means to determine the players' winning regions in the game; by determinacy it suffices to determine the winning region of one player. In the case of a *finite* game, there is an obvious interest in finding *efficient algorithms* for this task — one of the reasons for this interest lies in the connection with the *model checking* problem for the modal  $\mu$ -calculus that we will discuss in the next Chapter. The algorithmic angle also brings up the theoretical issue of the *computational complexity* of solving parity games, one of the most important open problems in the area. These algorithmic and complexity theoretic aspects of parity games form the topic of this section. Before going into the details we mention some notational and terminological conventions that apply in this section.

**Convention 5.36** In this section it will be convenient to admit the *empty* game: this allows for much simpler formulation of the recursion base of our algorithms. Furthermore, in the context of a fixed ambient game  $\mathcal{B}$ , we will write  $Attr_{\sigma}(A, D)$  rather than  $Attr_{\mathcal{B}_D}(A)$  for the attractor set of A in the subgame  $\mathcal{B}_D$ , and similarly we use  $Attr(\mathbb{B}, A)$  as the notation for the attractor set  $Attr^{\mathbb{B}}(A)$ . We will also frequently be sloppy about the distinction between a subset and the game it induces.

# 5.5.1 A quadratic algorithm for reachability games

We first consider the special case where the parity game is actually a reachability game; that is, we are interested in algorithms for computing attractor sets. The following theorem states that these games can be solved in *linear* time if we measure the board by its number of edges; obviously this algorithm is then *quadratic* in terms of the number of positions.

**Theorem 5.37** Let  $\mathbb{B} = (B_0, B_1, E)$  be some board  $\mathbb{B}$  and let  $A \subseteq B$  be a set of positions. Then there is an algorithm  $\mathbb{R}$  that computes the attractor set  $Attr(\mathbb{B}, A)$  and terminates in time  $\mathcal{O}(|E|)$ .

▶ Provide the algorithm and prove the theorem

# 5.5.2 An algorithm for solving parity games

As our starting point we take the algorithm  $\mathbf{Z}$  of Figure 4, which is basically the algorithmic presentation of our proof for positional determinacy in the finite case (Proposition 5.31). Based on some ambient parity game  $\mathcal{B}$ ,  $\mathbf{Z}$  computes, given a subgame G of  $\mathcal{B}$  with priorities up to some even number d, a subset  $solve_0(G, d)$  of G which constitutes exactly player 0's winning region in  $\mathbb{B}_G$ . Dually, in case d is odd  $\mathbf{Z}$  computes a subset  $solve_1(G, d)$  consisting of player 1's winning region .

The correctness of  $\mathbf{Z}$  is secured by the proof of Proposition 5.31, so we refrain from giving details here. For a rough complexity analysis of  $\mathbf{Z}$ , we focus on its recursive calls. We will think of the first of these, in line 4, as the main recursion, and of the second, in line 7, as an iteration — this perspective can be made precise by replacing the second recursive call with a while-loop. The depth of the main recursion is bounded by d, while the number of iterations is bounded by n. This means, basically, that the algorithm is polynomial in n, but exponential in d.

Algorithm Z: $solve_0(G, d)$			
1.	if $G=arnothing$ then return $G$		
2.	$M_d := \{ b \in G \mid \Omega(b) = d \}$		
3.	$H := G \setminus Attr_0(M_d, G)$		
4.	$A_1 := \texttt{solve}_1(H, d-1)$		
5.	$G_1 := G \setminus Attr_1(A_1, G)$		
6.	$W_0 := \mathtt{solve}_0(G_1, d)$		
7.	$\texttt{return} \ W_0$		

Figure 4: Basic algorithm **Z** for solving parity games

#### 5.5.3 A quasi-polynomial algorithm for solving parity games

Interestingly, the algorithm  $\mathbf{Z}$  for solving parity games that we discussed in the previous subsection can be upgraded to a so-called *quasi-polynomial* algorithm.

An algorithm is said to take quasi-polynomial time if its time complexity is quasi-polynomially bounded. This means that there is some constant c such that the algorithm, when given an input of size n, is guaranteed to stop after at most

$$2^{\mathcal{O}((\log n)^c)} \tag{52}$$

computation steps. Note that if we take c = 1 in (52) we obtain the class of all polynomial functions — the *degree* of the polynomial is given by the constant that is hidden in the  $\mathcal{O}$ -notation. If c > 1 the function will not be polynomial, but its growth rate will still be substantially smaller than exponential.

The idea underlying the upgrade of Z is that, instead of each recursive call of the procedure  $solve_{\sigma}$  completely solving a subgame, the algorithm will be based on a weaker assumption, viz., that each call of  $solve_{\sigma}$  returns a partition of the board that separates *small* paradises of the two players, up to a size specified by a pair or explicit parameters. The key observation is then that, in order to find all paradises for player  $\sigma$  of size, say, up to p, it suffices to search for all paradises of size up to  $\lfloor p/2 \rfloor$ , and at most one paradise of size  $\geq \lfloor p/2 \rfloor$ . (Recall that  $\lfloor q \rfloor$  denotes the largest natural number smaller than or equal to q.)

The quasi-polynomical upgrade  $\mathbf{L}$  of  $\mathbf{Z}$  is presented in Figure 5. Based on some ambient parity game  $\mathcal{B}$ ,  $\mathbf{L}$  computes a function  $\mathtt{solve}_0$  as follows. Given a subset G of B, again with priorities up to some even number d,  $\mathbf{L}$  returns a subset  $\mathtt{solve}_0(G, d, p_0, p_1) \subseteq G$  which contains all 0-paradises in  $\mathbb{B}_G$  of size up to  $p_0$ , and which does not intersect with any 1paradise in  $\mathbb{B}_G$  of size up to  $p_1$ . Dually,  $\mathbf{L}$  computes a map  $\mathtt{solve}_1(G, d, p_1, p_0)$  for player 1 and odd d.

The main observation about  $\mathbf{L}$  is that it makes *three* recursive calls, which compute three 'successive' subsets of  $G: G \supseteq G_1 \supseteq G_2 \supseteq G_3$ . The goal is then that  $G_3$  contains all 0paradises of size up to  $p_0$ ; and that the three recursive calls of  $\mathbf{L}$  collect all 1-paradises of size  $\leq p_1$  in  $G \setminus G_3$ , by successively fishing in  $G \setminus G_1, G_1 \setminus G_2$ , and  $G_2 \setminus G_3$ . Crucially, the first and third recursive call use only *half* of the precision parameter for 1-paradises: only the second call asks for full precision. The key step in the correctness proof of  $\mathbf{L}$  is that the first two

Α	Algorithm L: $solve_0(G, d, p_0, p_1)$			
1.	if $p_1=0$ then return $G$			
2.	if $p_0=0$ then return $arnothing$			
3.	if $d=0$ then return $Attr_0(G, arnothing)$			
4.	$G_1 := \texttt{solve}_0(G, d, p_0, \lfloor p_1/2  floor)$			
5.	$M_d := \{ b \in G_1 \mid \Omega(b) = d \}$			
6.	$H := G_1 \setminus Attr_0(M_d, G_1)$			
7.	$A_1:=\texttt{solve}_1(H,d{-}1,p_1,p_0)$			
8.	$G_2 := G_1 \setminus Attr_1(A_1, G_1)$

10.	$\texttt{return}~G_3$			

Figure 5: Quasi-polynomial algorithm L for solving parity games

recursive calls have already collected over the half of any 1-paradise of size  $p_0$ , so that the final call takes care of what is left.

**Theorem 5.38** Let  $\mathcal{B} = (B_0, B_1, E, \Omega)$  be a finite parity game, let  $d \ge \max(\operatorname{Ran}[\Omega])$  and let  $\sigma := d \mod 2$ . Then for any  $G \subseteq B$ , the algorithm  $\mathbf{L}$  returns a set  $\operatorname{solve}_{\sigma}(G, d, p_{\sigma}, p_{\overline{\sigma}})$  of nodes such that

(i)  $\operatorname{solve}_{\sigma}(G, d, p_{\sigma}, p_{\overline{\sigma}})$  contains each  $\sigma$ -paradise in  $\mathcal{B}_G$  of size up to  $p_{\sigma}$ ; and

(ii)  $\operatorname{solve}_{\sigma}(G, d, p_{\sigma}, p_{\overline{\sigma}})$  does not overlap with any  $\overline{\sigma}$ -paradise in  $\mathcal{B}_G$  of size up to  $p_{\overline{\sigma}}$ .

**Proof.** By induction on the sum  $d + p_0 + p_1$  we will prove the statements (i) and (ii), as well as the following statement:

(iii) the set  $solve_{\sigma}(B, d, p_{\sigma}, p_{\overline{\sigma}})$  is  $\sigma$ -closed.

As the basis of the induction we take the cases where at least one of d,  $p_0$  or  $p_1$  is zero. Since in any of these cases the proof is trivial, we may focus on the inductive case, where we may assume that d,  $p_0$  and  $p_1$  are all bigger than zero. Without loss of generality we assume that d is even, so that  $\sigma = 0$ . In the case where d is odd we proceed in a completely analogous way.

We start with proving the statement (iii). By the induction hypothesis we find that  $G_1$  is 0-closed in G, and that  $G_3$  is 0-closed in  $G_2$ . Hence by Proposition 5.26(4) it suffices to show that  $G_2$  is 0-closed in  $G_1$ . But this follows by Proposition 5.26(2), since  $G_2$  is the complement in  $G_1$  of a 1-attractor set.

In order to prove statement (i), let D be a 0-paradise in G of size at most  $p_0$ ; we need to show that  $D \subseteq G_3$ . This proof is depicted in Figure 6.

By the induction hypothesis we have  $D \subseteq G_1$ . Moreover, D is a 0-paradise in  $G_1$ : this follows from Proposition 5.33(3) and the fact that  $G_1 = G \setminus Attr_1(G \setminus G_1, G)$ , being the complement of a 0-attractor, is 1-closed in G. We now claim that

$$D$$
 is a 0-paradise in  $G_2$ . (53)

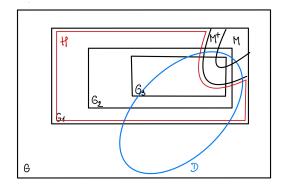

Figure 6: The proof of Theorem 5.38, part (i)

To prove this, we first observe that since H, being the complement of a 0-attractor set, is 1-closed in  $G_1$ , the intersection  $D' := D \cap H$  is a 0-paradise in H by Proposition 5.33(3). But since  $|D'| \leq |D| \leq p_0$ , by the induction hypothesis we find  $D' \cap A_1 = \emptyset$ ; but then by  $A_1 \subseteq H$ clearly we also have  $D \cap A_1 = D \cap H \cap A_1 = D' \cap A_1 = \emptyset$ . It follows that D is a 0-paradise in  $G_2$  by Proposition 5.33(2). This proves (53).

But this means that we are done since by the induction hypothesis, D being a 0-paradise in  $G_2$  implies that  $D \subseteq G_3$  as required.

Finally, we address statement (ii). Let D be a 1-paradise in G of size at most  $p_1$ ; we need to show that D has no overlap with  $G_3$ . This proof is depicted in Figure 7.

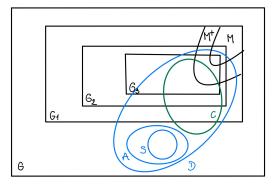

Figure 7: The proof of Theorem 5.38, part (ii)

Let S be the union of all 1-paradises in D of size at most  $\lfloor p_1/2 \rfloor$ , and let  $A := Attr_1(S, D)$  be its 1-attractor set in D. We first show that

$$A \cap G_1 = \emptyset. \tag{54}$$

But since D is 0-closed in G, by Proposition 5.26(5) we find that  $A \subseteq Attr_1(S, G)$  and that every 1-paradise in D is also a 1-paradise in G. Hence by the induction hypothesis we get

 $S \cap G_1 = \emptyset$ . But since  $G_1$  is 0-closed, the set  $A \subseteq Attr_1(S, G)$  does not overlap with  $G_1$ . This proves (54).

Now if A = D we are done since then we have  $D \cap G_3 = A \cap G_3 \subseteq A \cap G_1 = \emptyset$ . In the sequel we may therefor assume that  $A \subset D$ . This implies that  $D \setminus A$ , being 0-closed in D, is a (non-empty) 1-paradise in  $D \setminus A$  by Proposition 5.33(3). Then by Proposition 5.34, the set  $D \setminus A$  contains a nonempty 1-paradise C such that  $C \cap M = \emptyset$ . We now claim that

$$C \cup A$$
 is a 1-paradise in  $G$ , of size greater than  $|p_1/2|$ . (55)

We first show that  $C \cup A$  is a 1-paradise in D. To witness this, player 1 may use her positional winning strategy for positions in  $D \setminus A$ , the attractor strategy in D towards A for positions in  $A \setminus S$ , and the assumed positional winning strategy for any position in the 1-paradise S in D.

But D is 0-closed in G, and so this strategy works for 1 in G as well, for all nodes in  $C \cup A$ . It remains to show that  $C \cup A$  is of size greater than  $\lfloor p_1/2 \rfloor$ . Suppose for contradiction that  $|C \cup A| \leq \lfloor p_1/2 \rfloor$ ; then by definition of S we would find  $C \cup A \subseteq S$ , and since  $S \subseteq A$  this would contradict the fact that C is a nonempty subset of  $D \setminus A$ . This finishes the proof of (55).

Our next claim is that

$$(C \cup A) \cap G_2 = \emptyset. \tag{56}$$

Since  $G_1$  is 1-closed in G, by Proposition 5.33(3) the set  $(C \cup A) \cap G_1 = C \cap G_1$  is a 1-paradise in  $G_1$ , and, containing no vertices in M, also in H. Hence by the induction hypothesis, the set  $(C \cup A) \cap G_1$  does not intersect  $G_2$  (here we use that  $(C \cup A) \cap G_1 \subseteq D$ , so that  $|(C \cup A) \cap G_1| \leq |D| \leq p_1$ ). This proves (56).

But since  $G_2$  is 0-closed in G (as we saw in the proof of item (iii)), by Proposition 5.33(3) the set  $D \cap G_2$  is a 1-paradise in  $G_2$ . The key observation is now that because  $D \cap G_2$  has no overlap with  $C \cup A$  and  $|C \cup A| > \lfloor p_1/2 \rfloor$ , the size of  $D \cap G_2$  can be at most  $\lfloor p_1/2 \rfloor$ . But then a simple application of the induction hypothesis yields  $(D \cap G_2) \cap G_3 = \emptyset$ , which obviously implies  $D \cap G_3 = \emptyset$ . QED

With the correctness of  $\mathbf{L}$  established, we turn to its complexity analysis. The theorem below states that  $\mathbf{L}$  terminates in quasi-polynomial time, using quadratic space. In its proof we use the following arithmetical fact.

**Proposition 5.39** For any pair  $k, \ell$  of natural numbers we have

$$\binom{k}{\ell} \le \left(\frac{ek}{\ell}\right)^{\ell}.$$

**Proof.** Starting from the well-known fact that  $e^{\ell} = \sum_{j=0}^{\infty} \frac{\ell^j}{j!}$ , we find that  $\frac{\ell^{\ell}}{\ell!} < e^{\ell}$ , and from this we immediately infer that  $\frac{1}{\ell!} < \frac{e^{\ell}}{\ell^{\ell}}$ . This gives  $\binom{k}{\ell} \leq \frac{k^{\ell}}{\ell!} \leq \left(\frac{ek}{\ell}\right)^{\ell}$ . QED

**Theorem 5.40** Let  $\mathcal{B}$  be a parity game with n positions and maximal priority d. Then the algorithm  $\mathbf{L}$  computes the winning regions of  $\mathcal{B}$  in time

$$2^{\mathcal{O}\left(\log n \cdot \log\left(1 + \frac{d}{\log n}\right)\right)},$$

and space  $\mathcal{O}(n^2)$ .

**Proof.** Let  $R(d, \ell)$  be the maximum number of calls to  $solve_0$  and  $solve_1$  during an execution of  $solve_{\sigma}$ , where  $\sigma = d \mod 2$  and  $\ell := \lfloor \log p_0 \rfloor + \lfloor \log p_1 \rfloor$ . We only consider the cases where  $p_0, p_1 \ge 1$ , so that we have  $\ell \ge 0$ .

By induction on  $d + \ell$  we show that

$$R(d,\ell) \le 2^{\ell+1} \cdot \binom{d+\ell}{\ell} - 1.$$
(57)

We take the basis of this induction to be the cases where d = 0; here we may easily verify (57) by calculating  $R(d, \ell) = 0 \le 2^{\ell+1} - 1 = 2^{\ell+1} \cdot {\binom{0+\ell}{\ell}} - 1$ .

In the inductive step of the proof we may then assume that  $d \ge 1$ , so that a straightforward inspection of the algorithm shows that  $R(d, \ell) \le 1 + 2 \cdot R(d, \ell - 1) + R(d - 1, \ell)$ . This leads to the following calculation:

$$\begin{aligned} R(d,\ell) &\leq 1+2 \cdot R(d,\ell-1) + R(d-1,\ell) \\ &\leq 2 \cdot 2^{(\ell-1)+1} \cdot \left( \binom{d+(\ell-1)}{\ell-1} - 1 \right) + 2^{\ell+1} \cdot \binom{(d-1)+\ell}{\ell} - 1 \quad \text{(induction)} \\ &= 2^{\ell+1} \cdot \left( \binom{d+(\ell-1)}{\ell-1} + \binom{d+(\ell-1)}{\ell} \right) - 1 \\ &= 2^{\ell+1} \cdot \binom{d+\ell}{\ell} - 1 \end{aligned}$$

as required for proving (57).

We now apply the inequality  $\binom{k}{\ell} \leq \left(\frac{ek}{\ell}\right)^{\ell}$  from Proposition 5.39 for  $k = d + \ell$  and obtain

$$R(d,\ell) \le 2^{\ell+1} \cdot \left(\frac{e \cdot (d+\ell)}{\ell}\right)^{\ell} \le 2 \cdot \left(\frac{2e \cdot (d+\ell)}{\ell}\right)^{\ell} \le 2 \cdot 2^{\ell \cdot \left(1 + \log e + \log(1 + \frac{d}{\ell})\right)}$$

In a parity game with n vertices, we start with  $\ell = 2 \cdot \lfloor \log n \rfloor$ , finding

$$R(d, 2 \cdot \lfloor \log n \rfloor) \le 2 \cdot 2^{2 \cdot \lfloor \log n \rfloor \cdot \left(1 + \log e + \log(1 + \frac{d}{2 \cdot \lfloor \log n \rfloor})\right)}$$

Finally, the cost of each call, apart from the recursive calls, is dominated by the construction of the attractor sets in the lines 6 and 8. Since we obtain by Theorem 5.37 that there are algorithms for computing attractor set that runs in time quadratic in the size of the vertices, this means that the run time of  $\mathbf{L}$  is bounded by

$$n^2 \cdot 2 \cdot 2^{2 \cdot \lfloor \log n \rfloor \cdot \left(1 + \log e + \log(1 + \frac{d}{2 \cdot \lfloor \log n \rfloor})\right)}$$

and hence in  $2^{\mathcal{O}\left(\log n \cdot \log\left(1 + \frac{d}{\log n}\right)\right)}$  as stated by the theorem.

▶ say something about space complexity

Lectures on the modal  $\mu$ -calculus

**Remark 5.41** Generally the index of a parity game is small when compared to its size. If we have  $d = \mathcal{O}(\log n)$  the complexity of **L** is bounded by  $2^{\mathcal{O}(\log n)}$ . This means that it runs in *polynomial* time, where the degree of the polynomial that provides an upper bound is 'hidden' in the  $\mathcal{O}$ -notation.

 $\triangleleft$ 

### 5.6 Game equivalence

In this section we explore some notions of *equivalence* for board games. In this setting we will frequently represent a board as a triple  $\mathbb{B} = \langle B, E, \sigma \rangle$ , where  $\sigma : B \to \{0, 1\}$  is a map assigning a player to each position in B.

### 5.6.1 Simple shadow games

In this book we often use the technique of 'shadow matching' to supply a player  $\sigma$  with a winning strategy in some initialised game  $\mathcal{B}@b$ , using a winning strategy for  $\sigma$  in some similar, related initialised game  $\mathcal{B}'@b'$ . These proofs follow a common pattern that we bring out here, starting with the notion of a *(simple) shadow simulation*. For its definition we recall the definition of the *lifted* version  $\widetilde{Z} \subseteq A^{\infty} \times B^{\infty}$  of a relation  $Z \subseteq A \times B$ :

$$\widetilde{Z} := \left\{ \left( (a_i)_{0 \le i < \kappa}, (b_i)_{0 \le i < \lambda} \right) \mid \kappa = \lambda \text{ and } (a_i, b_i) \in Z, \text{ for all } i \right\}.$$

**Definition 5.42** Let  $\mathcal{B} = \langle B, E, \sigma, W \rangle$  and  $\mathcal{B}' = \langle B', E', \sigma', W' \rangle$  be board games. A relation  $Z \subseteq B' \times B$  is called a *(simple) shadow simulation* if it meets the following conditions:

- 1. Z repects players: if  $(b', b) \in Z$  then  $\sigma'(b') = \sigma(b)$ ;
- 2. Z respects winners: for finite matches we require that if  $(b', b) \in Z$  then we have  $E'[b] = \emptyset$  iff  $E[b] = \emptyset$ ; for infinite matches we require that  $(\pi', \pi) \in \widetilde{Z}$  implies  $W'(\pi') = W(\pi)$ .

Given a shadow simulation Z, any pair  $(\pi', \pi) \in \widetilde{Z}$  is called a *shadow pair*, where we refer to  $\pi'$  as a *shadow match* of  $\pi$ .

Shadow simulations can be used to transfer winning strategies from one game to another. The key idea here is that a player may win a match of a  $\mathcal{B}'$ -game by maintaining a safe connection with a shadow match of  $\mathcal{B}$  that is guided by her winning strategy.

**Definition 5.43** Let  $\mathcal{B} = \langle B, E, \sigma, W \rangle$  and  $\mathcal{B}' = \langle B', E', \sigma', W' \rangle$  be board games, linked by a shadow simulation  $Z \subseteq B' \times B$ . Furthermore, let f' be a strategy for  $\sigma$  which is winning for each of her winning positions in  $\mathcal{B}'$ . Then a shadow pair  $(\pi', \pi)$  is called *safe for*  $\sigma$  (relative to f) if first $(\pi') \in \operatorname{Win}_{\sigma}(\mathcal{B}')$  and  $\pi'$  is f'-guided.

We say that Z satisfies the safe continuation condition (scc) with respect to f, if for every safe shadow pair  $(\pi', \pi)$ , we have, writing  $a := \text{first}(\pi)$  and  $a' := \text{first}(\pi')$ :

- 1) if  $a \in B_{\sigma}$  then  $(f'(\pi'), b) \in Z$ , for some  $b \in E[a]$ ;
- 2) if  $a \in B_{\overline{\sigma}}$  then for all  $b \in E[a]$  there is some  $b' \in Z$  such that  $(b', b) \in Z$ .

The key result about shadow simulations is the following; we leave its proof as an exercise for the reader.

**Theorem 5.44 (Shadow Play Theorem)** Let  $\mathcal{B} = \langle B, E, \sigma, W \rangle$  and  $\mathcal{B}' = \langle B', E', \sigma', W' \rangle$ be board games, linked by a shadow simulation  $Z \subseteq B' \times B$ , and let f' be a strategy for  $\sigma$  which is winning for each of her winning positions in  $\mathcal{B}'$ . Furthermore, assume that Z satisfies the safe continuation conditions with respect to f. Then for every pair  $(b, b') \in Z$  we find that  $b' \in Win_{\sigma}(\mathcal{B}')$  implies  $b \in Win_{\sigma}(\mathcal{B})$ . Note that the safe continuation condition refers to *both* matches of the shadow pair. The following example may clarify why this is needed.

**Example 5.45** Let  $\mathcal{B}, \mathcal{B}', f'$  and Z be as in Definition 5.43. Call a  $\mathcal{B}$ -match  $\pi$  safe if it is part of a safe shadow pair  $(\pi', \pi)$ . Furthermore, say that Z satisfies the weak safe continuation condition (wscc) if every safe  $\mathcal{B}$ -match  $\pi$  is either full, and won by  $\sigma$ , or else it has a safe extension. The following example reveals that this does not suffice to transfer f' to a winning strategy in  $\mathcal{B}$ .

We compare two models  $\mathbb{S} = (S, R, V)$  and  $\mathbb{S}' = (S', R', V')$ , where  $S = S' := \omega \cup \{\infty\}$ ,  $R' = >, R = > \cup \{(\infty, \infty)\}$ , and V = V' is arbitrary. These models can be used to show that bisimilarity does not coincide with equivalence in the basic modal language, but they are also of interest here. Clearly we have, with  $\varphi := \mu x. \Box x$  that  $\mathbb{S}, \infty \Vdash \varphi$  while  $\mathbb{S}', \infty \not\models \varphi$ . In game-theoretic terms, writing  $\mathcal{B} := \mathcal{E}(\varphi, \mathbb{S})$  and  $\mathcal{B}' := \mathcal{E}(\varphi, \mathbb{S}')$ , we find  $(\varphi, \infty) \in \operatorname{Win}_{\exists}(\mathcal{B})$ but  $(\varphi, \infty) \notin \operatorname{Win}_{\exists}(\mathcal{B}')$ . Now consider the relation

$$Z := \Big\{ \big((\psi, s), (\psi, s)\big) \mid s \in S, \psi \in Cl(\varphi) \Big\} \cup \Big\{ \big((\psi, n), (\psi, \infty)\big) \mid n \in \omega, \psi \in Cl(\varphi) \Big\}.$$

The point is that Z satisfies the *weak* safe continuation condition, while obviously, the position  $(\varphi, \infty)$  is linked to itself by Z. This provides a counterexample to the weaker version of Theorem 5.44 where we merely require Z to satisfies the wscc.

 $\blacktriangleright$  discuss generalisations: may link  $\sigma$  to their opponent as well

## 5.6.2 Covers

# The material in this subsection needs to be properly checked

A very tight link between two games arises if one is a *cover* of the other. Intuitively,  $\mathcal{B}$  is a cover of  $\mathcal{B}'$  if it is some kind of (finitary) unravelling of  $\mathcal{B}'$ , witnessed by some *cover map* f. In order to define the conditions on these cover maps, we remind the reader of the following notation: where  $f: B \to B'$  is some map, and  $\pi \in B^{\infty}$  is some (finite or infinite) *B*-sequence, say,  $\pi = (b_i)_{0 \le i \le \kappa}$ , we let  $f \circ \pi$  denote the *B'*-sequence  $f \circ \pi := (fb_i)_{0 \le i \le \kappa}$ .

**Definition 5.46** Let  $\mathbb{B} = \langle B, E, \sigma \rangle$  and  $\mathbb{B}' = \langle B', E', \sigma' \rangle$  be two boards, and let  $h : B' \to B$ and  $j : B \to B'$  be two functions. Then we call h and j a *pair of cover maps* for  $\mathbb{B}$  and  $\mathbb{B}'$  if h is surjective, j is injective and h and j satisfy the following conditions:

1) h(j(b)) = b, for all  $b \in B$ ;

- 2) h restricts to a bijection between the sets E'[b'] and E[h(b')], for every  $b' \in B'$ ;
- 2) h respects ownership:  $\sigma(h(b')) = \sigma(b')$ , for every  $b' \in B'$ .

For two board games  $\mathcal{B} = \langle B, E, \sigma, W \rangle$  and  $\mathcal{B}' = \langle B', E', \sigma', W' \rangle$ , we call such a pair (h, j) a pair of cover maps if in addition we have

4) h and j respect winners:  $W(\pi') = W(h \circ \pi')$ , for every infinite  $\mathcal{B}'$ -match  $\pi'$  such that  $j(h(\text{first}(\pi')) = \text{first}(\pi')$ .

In the case of initialised games, we call  $\mathcal{B}'@b'$  a cover of  $\mathcal{B}@b$  if there is a pair (h, j) of cover maps with j(b) = b'. If h and j are a pair of cover maps for  $\mathcal{B}$  to  $\mathcal{B}'$ , we call  $\mathcal{B}'$  a cover of  $\mathcal{B}$ , and we use similar terminology and notation for initialised games.

Cover maps resemble bounded morphisms between Kripke models, but the bijection condition on successor sets is much stronger than the back- and forth condition of bounded morphisms.

We gather some basic facts about covers and cover maps. Our first observation is that, if h and j form a pair of cover maps from  $\mathbb{B}'$  to  $\mathbb{B}$ , then for any position  $b' \in B'$  there is a 1-1 correspondence between  $\mathbb{B}'$ -paths starting at b' and  $\mathbb{B}$ -paths starting at h(b').

**Proposition 5.47** Let  $\mathbb{B} = \langle B, E, \sigma \rangle$  and  $\mathbb{B}' = \langle B', E', \sigma' \rangle$  be two boards, and let  $h : B' \to B$ and  $j : B \to B'$  be a pair of cover maps. Then for any path  $\pi$  in  $\mathbb{B}$  and every  $b' \in B'$  such that  $h(b) = \text{first}(\pi)$ , there is a unique path  $\pi'$  in  $\mathbb{B}'$  such that  $\pi = h \circ \pi'$ .

At the level of games, Proposition 5.47 means that the cover map induces a bijection between the matches of an initialised game and any of its covers. Formulated in terms of game trees, we even find an *isomorphism*, which is sometimes taken as a reason to *identify* a game with its covers.

**Proposition 5.48** Let  $a \in B$  be some position in the board game  $\mathcal{B} = \langle B, E, \sigma, W \rangle$ . Then

- 1. the tree game  $\mathcal{B}_a^T$  @a covers  $\mathcal{B}$  @a, via the pair (last, j) of cover maps, where j maps a position  $b \in B$  to the one-step path b;
- 2. if  $\mathcal{H}$  covers  $\mathcal{B}$  witnessed by the pair (h, j), then  $\mathcal{B}_a^T \cong \mathcal{H}_{j(a)}^T$ , for any a in  $\mathcal{B}$ .

The following Proposition, the proof of which is left for the reader, states that cover maps preserve winning regions.

**Proposition 5.49** Let  $\mathcal{B}'$  cover  $\mathcal{B}'$ , witnessed by the pair (h, j) of cover maps. Then for each player  $\sigma \in \{0, 1\}$  and each  $b \in B$  we have  $b \in Win_{\sigma}(\mathcal{B})$  iff  $j(b) \in Win_{\sigma}(\mathcal{B}')$ .

As an important example of a cover map, the following proposition states that every  $\omega$ -regular game is covered by a parity game.

**Proposition 5.50 (Parity Cover Lemma)** Let  $\mathcal{B} = \langle B, E, \sigma, W \rangle$  be an  $\omega$ -regular game, and let M be any deterministic parity automaton recognizing the  $\omega$ -regular language used to define W. Then  $\mathcal{B}$  is covered by a parity game which is based on the set  $B \times M$ .

**Proof.** See Exercise 5.2.

QED

The following observation is an immediate corollary of the Cover Lemma and Proposition 5.49.

**Corollary 5.51** Let  $\mathcal{B}$  be an  $\omega$ -regular game. Then  $\mathcal{B}$  is determined.

The concept of cover game allows us to manipulate some structural properties of board games. For instance, the following Proposition shows how covers may be used to confine the domain of a partial priority map to the pre-image of any cycle-critical subset of the board of the covered game. Lectures on the modal  $\mu$ -calculus

**Proposition 5.52 (Strengthened Parity Cover Lemma)** Let  $\mathcal{B} = \langle B, E, \sigma, W \rangle$  be an  $\omega$ -regular game. Then  $\mathcal{B}$  is covered by a ppm-parity game  $\mathcal{B}' = \langle B', E', \sigma', \Omega' \rangle$  through a pair (h, j) of cover maps. Furthermore,

- 1. if  $D \subseteq B$  is cycle-critical, then we may assume that  $\mathsf{Dom}(\Omega') \subseteq h^{-1}[D]$ ;
- 2. if  $D \subseteq B$  is cycle-critical and  $E \cap (D \times D) = \emptyset$ , then we may assume injectivity of E' on  $f^{-1}[D]$ : if  $f(u'_i) \in D$  and  $(u'_i, v') \in E'$ , for i = 0, 1, then  $u'_0 = u'_1$ .

**Proof.** By the standard parity cover lemma we may without loss of generality assume that  $\mathcal{B}$  is itself already a (standard) parity game, say, with (total) priority map  $\Omega: B \to \omega$ . Based on this we will take care of the two parts of the proposition.

For part 1, assume that  $D \subseteq B$  is cycle-critical, and define  $\mathcal{B}' := \langle B', E', \sigma', \Omega' \rangle$  as follows.

The intuition underlying this construction is as follows. A position (u, k) represents a path  $\pi$  in  $\mathcal{B}$  such that  $u = \mathsf{last}(\pi)$  and u may be the only position on  $\pi$  that belongs to D, while k is a counter that records the highest priority encountered on  $\pi$ . The value k is reset following a position  $u \in D$ ; that is, if  $(v, m) \in E(u, k)$  and  $u \in D$  then the value of m is no longer dependent on any value encountered on the path before v, but simply defined as the priority of v.

We claim that the projection map  $(u, k) \mapsto u$  together with the inclusion  $u \mapsto (u, \Omega(u))$ provide the required pair of cover maps for  $\mathcal{B}'$  and  $\mathcal{B}$ . The details of verifying this claim are left as an exercise for the reader.

For part 2, assume that  $D \subseteq B$  is cycle-critical and that  $E \cap (D \times D) = \emptyset$ . Now we define

$$\begin{array}{lll} B' & := & ((B \setminus D) \times B) \cup (D \times \{*\}) \\ E'[(u,x)] & := & \left\{ (v,u) \mid v \in E[u] \setminus D \right\} \right\} \cap \left\{ (v,*) \mid v \in E[u] \cap D \right\} \right\} \\ \sigma'(u,x) & := & \sigma(u) \\ \Omega'(u,x) & := & \left\{ \begin{array}{ll} \Omega(u) & \text{if } u \in \mathsf{Dom}(\Omega) \\ \text{undefined otherwise} \end{array} \right. \end{array}$$

Here the intuition underlying the definition of B' is also that a position (v, y) is basically a version of  $v \in B$ , with y providing some record of v's 'provenance', so to say. More precisely, if  $(v, y) \in E'[(u, x)]$  then we always have  $v \in E[u]$ ; in addition we 'remember' u if  $v \notin D$  (in the sense that y = u), while we 'forget' u if  $v \in D$  (in the sense that y = \*).

To see that E' is injective on  $f^{-1}[D]$ , suppose that we have  $(v, y) \in E'[(u_0, x_0)] \cap E'[(u_1, x_1)]$  for  $u_0, u_1 \in D$ . But since  $u_0, u_1 \in D$  we can only have  $x_0 = x_1 = *$ . Furthermore,  $u_i \in D$  implies  $v \notin D$  by the assumption on E, so that by definition of E' we find  $y = u_i$  for i = 0, 1. But then we have  $(u_0, v_0) = (u_1, v_1)$  indeed.

5 - 26

As in the proof of the previous claim, we leave it for the reader to verify that the projection map  $(u, k) \mapsto u$ , now with partial converse j given by j(u) := (u, u) if  $u \in D$  and j(u) := (u, \*) otherwise, provides the required cover map. QED

## 5.6.3 Game bisimulations

In the previous subsections we saw examples of rather *tight* links between two games. Here we introduce a notion of game bisimulation which is more general, in at least two ways.

First, game bisimulations do not necessarily link a player in one game to the *same* player in the oppositie game. This is for instance useful if we want to give a game-theoretic proof that the formula  $\overline{\varphi}$  of Definition 3.22 indeed corresponds to the negation of the formulas  $\varphi$ .

Second, game bisimulations do not need to link *every* position in one of the two games to some position in the other; rather we select some key positions in both games, and we only require that the bisimulation links key positions in one game to key positions in the other. This is for instance useful in a situation where we compare evaluation games for formulas that are equivalent.

▶ Details to be supplied.

**Definition 5.53** Given an graph game  $\mathcal{B} = (B_0, B_1, E, W)$ , call a subset  $A \subseteq B_0 \cup B_1$  of positions *prime* if it satisfies the following two conditions:

- 1. any infinite full match starting at some  $b \in A$  passes through another position in A;
- 2. the winner of an infinite match is completely determined by the sequence of positions in A induced by the match.

By a slight abuse of language we refer to the elements of a fixed, prime set as *prime positions*.  $\lhd$ 

**Remark 5.54** To spell out the second condition, in the appendix we formally define what we mean with 'the sequence of positions in A, induced by  $\pi'$ . Where  $\pi_{\uparrow A}$  denotes this induced sequence, condition 2 states that that two matches  $\pi$  and  $\pi'$  have the same winner if  $\pi_{\uparrow A} = \pi'_{\uparrow A}$ . Furthermore, note that, given the first condition,  $\pi_A$  is an infinite sequence if  $\pi$  is infinite.

▶ Examples to be added.

The point about the introduction of prime positions is that, just as in the case of acceptance games of modal automata, they allow us to think of the game proceeding in *rounds* that start and finish at a prime position (unless one of the players gets stuck during the round). Formally we define these rounds, that correspond to subgraphs of the board graph, via their unravellings as follows.

**Definition 5.55** Let A be some prime set of positions in a graph game  $\mathcal{B} = (B_0, B_1, E, W)$ , and let  $a \in A$  be a prime position. The *neighbourhood game tree* associated with a is defined as the following tree  $\mathbb{T}^a := (T^a, E^a, a)$ ; here  $T^a$  is the set of all paths  $\beta$  in (B, E), starting in a, and of which the only prime positions are a and  $\mathsf{last}(\beta)$  (in case it is prime). We let  $T^a$  inherit the partition of B, by putting  $T^a_{\sigma} := \{\beta \in T^a \mid \mathsf{last}(\beta) \in B_{\sigma}\}$ ;  $E^a := \{(\beta, \beta b) \mid b \in E[\mathsf{last}(\beta)]\}$ is the one-item extension relation on paths, and the one-state path a is the root of  $\mathbb{T}^a$ . It follows from the definitions that all branches of  $\mathbb{T}^a$  are finite. Clearly  $\mathbb{T}^a$  is a subtree of the game tree of the initialized game  $\mathcal{B}@b$ , where we only take those finite matches that start at the prime position a and that end either because one the players gets stuck, or because a new prime position is reached.

**Definition 5.56** Let A be some prime set of positions in a graph game  $\mathcal{B} = (B_0, B_1, E, W)$ , and let  $a \in A$  be a prime position. A node  $\beta \in T^a$  is a *prime leaf* of  $\mathbb{T}^a$  if  $|\beta| > 1$  and  $\mathsf{last}(\beta) \in A$ ; we denote the set of these leaves as  $\mathsf{PrL}(b)$ , and write  $N(a) := \{\mathsf{last}(\beta) \mid \beta \in \mathsf{PrL}\}$ .

Prime leaves of  $\mathbb{T}^a$  represent full rounds of  $\mathcal{B}$  starting at a, that is, partial matches that start at a and end because a second prime position has been reached. Intuitively then, the set N(a) denotes the set of all positions that one may encounter in such a round of  $\mathcal{B}$ . Non-prime leafs correspond to full matches in which one of the two players gets stuck before a next prime position is met. These intuitions will be made precise in Proposition 5.60 below.

Once we have established a disection of a graph game using prime positions, we may think of the game being in an 'iterative strategic normal form', in the sense that in each round, each player only makes *one choice*, announcing their complete strategy for that round right at the beginning. This idea will be formalized below in two ways, using, respectively, the notion of a player's *power* and that of a *neighbourhood strategy*. Underlying both approaches is the notion of a *neighbourhood game*; different from the games that we have seen so far this game can end in a *draw*.

**Definition 5.57** Let  $\mathcal{B} = (B_0, B_1, E, W)$  be a board game, with a prime set  $A \subseteq B$ , and let  $a \in A$  be a prime position. The *neighbourhood game*  $\mathcal{B}^a$  induced by a is played on the board  $(B_0^a, B_1^a, E^a))$ , where  $B_{\sigma}^a := \{ \mathsf{last}(\beta) \mid \beta \in T^a \cap B_{\sigma} \}$ , and  $E^a := \{ (b, c) \in E \mid b = a \text{ or } b \in B \setminus A \}$ . Noting that all matches played on this board are finite, we declare a match  $\pi$  of  $\mathcal{B}^a$  to be a *draw* if  $|\pi| > 1$  and  $\mathsf{last}(\pi)$  is a prime position; in all other cases one of the players got stuck, and we declare their opponent to be the winner.

It is easy to see that  $\mathbb{T}^a$  is the game tree of  $\mathcal{B}^a$ . The game-theoretic notion of *power* describes the terminal positions which a player can force in this game by deploying a strategy.

**Definition 5.58** Let A be a prime set relative to some board game  $\mathcal{B} = (B_0, B_1, E, W)$ , and let a be a prime position. By induction on the height of a node  $\beta \in T^a$  we define, for each player  $\sigma$ , the *power* of  $\sigma$  at a as a collection  $P_{\sigma}(\beta) \subseteq N(a)$  of subsets of N(a).

- if  $\beta \in \mathsf{PrL}$ , we define for each player  $\sigma$ :

$$P_{\sigma}(\beta) := \big\{ \{ \mathsf{last}(\beta) \} \big\};$$

- if  $\beta \notin \mathsf{PrL}$ , we put

$$P_{\sigma}(\beta) := \begin{cases} \bigcup \left\{ P_{\sigma}(\beta c) \mid c \in E^{a}[\mathsf{last}(\beta)] \right\} & \text{if } \beta \in T_{\sigma}^{a} \\ \left\{ \bigcup_{c \in E^{a}[\mathsf{last}(\beta)]} Y_{c} \mid Y_{c} \in P_{\sigma}(\beta c), \text{ all } c \right\} & \text{if } \beta \in T_{\overline{\sigma}}^{a} \end{cases}$$

Parity games

 $\triangleleft$ 

Finally, we define the power of  $\sigma$  at a as the set  $P_{\sigma}(a)$ .

The first clause of the definition should be clear: at the end of a round of  $\mathcal{B}$ , the players have no influence on the outcome any more. For some intuitive explanation of the second clause, we distinguish the two cases. If  $\beta \in T^a_{\sigma}$ , then in  $\mathcal{B}^a$ , when play has arrived at the match  $\beta$ ,  $\sigma$  may choose a successor c of  $\mathsf{last}(\beta)$ , and hence  $P_{\sigma}(\beta)$  consists of those sets that  $\sigma$ can pick at any of the continuationss  $\beta c$  of  $\beta$ . On the other hand, if  $\beta \in T^a_{\overline{\sigma}}$ , then  $\sigma$  has no influence on the choice of a successor c of  $\mathsf{last}(\beta)$ , so the best  $\sigma$  can do is the following. If  $\sigma$ picks, for each  $c \in E^a[\mathsf{last}(\beta)]$ , a set  $Y_c \in P_{\sigma}(\beta c)$ , then the union of these sets does belong to her power at  $\beta$ .

Perhaps some special attention is due to the paths  $\beta \in T^a$  such that  $E^a[\beta] = \emptyset$ . In case such a  $\beta$  is a prime leaf, we follow the first clause of Definition 5.58; intuitively, this means that  $E[\mathsf{last}(\beta)]$  being empty will not be noticed in this round of  $\mathcal{B}$ , but only at the beginning of the next one. In case  $E^a[\beta] = \emptyset$  for some non-prime leaf, we obtain, by the second clause of the definition, that

$$P_{\sigma}(\beta) := \begin{cases} \varnothing & \text{if } \beta \in T_{\sigma}^{a} \\ \{\varnothing\} & \text{if } \beta \in T_{\overline{\sigma}}^{a}. \end{cases}$$

This confirms our intuition that at such a position, the player who is to move gets stuck and looses the match.

As we will see now, the powers of the two players can also be formulated in terms of strategies in the neighbourhood game.

**Definition 5.59** Let A be a prime set relative to some board game  $\mathcal{B} = (B_0, B_1, E, W)$ , and let a be a prime position. A *neighbourhood strategy* of a player  $\sigma$  is simply a strategy for  $\sigma$  in the neighbourhood game. Such a neighbourhood strategy is *surviving* for  $\sigma$  if it guarantees that  $\sigma$  will not get stuck (in  $\mathcal{B}^a$ ), and *winning* if it guarantees that  $\overline{\sigma}$  gets stuck (in  $\mathcal{B}^a$ ).

If players 0 and 1 play  $\mathcal{B}^a$  using, respectively, neighbourhood strategies  $f_0$  and  $f_1$ , then the unique resulting match will be denoted as  $\operatorname{res}(f_0, f_1)$ . Given a neighbourhood strategy  $f_0$ for player 0, we define

 $X_{f_0} := \{ \mathsf{last}(\mathsf{res}(f_0, f_1)) \in A \mid f_1 \text{ is a neighbourhood strategy for player } 1 \},\$ 

and similarly we define  $X_{f_1}$  for a neighbourhood strategy for player 1.

 $\triangleleft$ 

Obviously, neighbourhood strategies for  $\sigma$  are linked to (fragments of) strategies for  $\sigma$  in  $\mathcal{B}$ . Since these links are generally obvious, but rather tedious to spell out, we refrain from introducing detailed notation and terminology here.

The next proposition spells out the link between neighbourhood strategies and the power of players. We leave its proof as an exercise to the reader.

**Proposition 5.60** Let A be a prime set relative to some board game  $\mathcal{B} = (B_0, B_1, E, W)$ , and let a be some prime position. Then the following hold, for either player  $\sigma$ :

- 1)  $P_{\sigma}(a) = \emptyset$  iff  $\overline{\sigma}$  has a winning neighbourhood strategy in  $\mathcal{B}^a$ ;
- 2)  $\emptyset \in P_{\sigma}(a)$  iff  $\sigma$  has a winning neighbourhood strategy in  $\mathcal{B}^a$ ;
- 3) for any nonempty  $W \subseteq N(a)$  it holds that

 $W \in P_{\sigma}(a)$  iff  $W = X_f$  for some surviving neighbourhood strategy f for  $\sigma$  in  $\mathcal{B}^a$ .

The partitioning of matches of a board game  $\mathcal{B}$  into rounds, moving form one prime position to another, and the analysis of the players' powers in one round of such a match, lay the foundations to the introduction of a structural equivalence relation between board games that we refer to as *prime game bisimulation*.

For its definition we recall how to *lift* a binary relation Z between objects to a relation  $\widetilde{Z}$  between sequences of these objects. Where  $Z \subseteq S \times S'$ ,  $\pi = (s_i)_{0 \leq i < \kappa} \in S^{\infty}$  and  $\pi' = (s'_i)_{0 \leq i < \lambda} \in S'^{\infty}$ , we put  $(\pi, \pi') \in \widetilde{Z}$  iff  $\kappa = \lambda$  and  $(s_i, s'_i) \in Z$ , for all  $i < \kappa$ .

**Definition 5.61** Let  $\mathcal{B} = (B_0, B_1, E, W)$  and  $\mathcal{B}' = (B'_0, B'_1, E', W')$  be two board games, with prime sets A and A', respectively, and let  $\sigma$  and  $\sigma'$  be (not necessarily distinct) players in  $\mathcal{B}$  and  $\mathcal{B}'$ , respectively.

A  $(\sigma, \sigma')$ -game bisimulation is a binary relation  $Z \subseteq A \times A'$  which satisfies the following compatibility condition:

if 
$$\pi \in B^{\omega}$$
 and  $\pi' \in B'^{\omega}$  are such that  $(\pi \upharpoonright_A, \pi \upharpoonright_{A'}) \in \widetilde{Z}$ , then  $W(\pi) = \sigma$  iff  $W'(\pi') = \sigma'$ ,  
(58)

as well as the following back-and-forth condition:

$$(P^{\mathcal{B}}_{\sigma}(a), P^{\mathcal{B}'}_{\sigma'}(a')) \in \overrightarrow{\wp} \overleftarrow{\wp}(Z) \cap \overleftarrow{\wp} \overrightarrow{\wp}(Z),$$
(59)

for every  $a \in A$  and  $a' \in A'$  with  $(a, a') \in Z$ .

Unravelling the rather concise statement (59), we find that the back-and-forth condition boils down to the following requirements:

$$\begin{array}{ll} (\sigma, \mathrm{forth}) & \forall W \in P_{\sigma}^{\mathcal{B}}(a) \, \exists W' \in P_{\sigma'}^{\mathcal{B}'}(a') \, \forall b' \in W' \, \exists b \in W. \, (b,b') \in Z \\ (\overline{\sigma}, \mathrm{forth}) & \forall W \in P_{\overline{\sigma}}^{\mathcal{B}}(a) \, \exists W' \in P_{\overline{\sigma'}}^{\mathcal{B}'}(a') \, \forall b' \in W' \, \exists b \in W. \, (b,b') \in Z \\ (\sigma', \mathrm{back}) & \forall W' \in P_{\sigma'}^{\mathcal{B}'}(a') \, \exists W \in P_{\sigma}^{\mathcal{B}}(a) \, \forall b \in W \, \exists b' \in W'. \, (b,b') \in Z \\ (\overline{\sigma'}, \mathrm{back}) & \forall W' \in P_{\overline{\sigma'}}^{\mathcal{B}'}(a') \, \exists W \in P_{\overline{\sigma}}^{\mathcal{B}}(a) \, \forall b \in W \, \exists b' \in W'. \, (b,b') \in Z. \end{array}$$

Given the symmetries in this definition, it should be clear that there are only two kinds of game bisimulations: the (0,0)-bisimulations coincide with the (1,1)-bisimulations, and the (0,1)-bisimulations with the (1,0)-bisimulations.

**Example 5.62** Clearly our definition of the compatibility condition (58) does not follow the idea that bisimulation-like conditions should be 'local' in some sense. But then again, this is hardly possible since at this level of generality the winning conditions themselves are non-local. In many cases where the winning conditions are given by a more local definition we can significantly improve on this.

In particular, in case  $\mathcal{B} = (B_0, B_1, E, \Omega)$  and  $\mathcal{B}' = (B'_0, B'_1, E', \Omega')$  are *parity* game, we may require the following two conditions:

(matching parities) if  $(v, v') \in Z$  then  $\Omega(v) \mod 2 = \sigma$  iff  $\Omega'(v') \mod 2 = \sigma'$ ;

(contraction) if  $(v, v'), (w, w') \in Z$  then  $\Omega(v) \leq \Omega(w)$  iff  $\Omega'(v') \leq \Omega'(w')$ .

 $\triangleleft$ 

We leave it for the reader to verify that any relation satisfying these two conditions also meets the compatibility constraint (58).  $\triangleleft$ 

The following theorem bears witness to the fact that game bisimulation is indeed a useful notion of structural equivalence between board games.

**Theorem 5.63** Let  $\mathcal{B} = (B_0, B_1, E, W)$  and  $\mathcal{B}' = (B'_0, B'_1, E', W')$  be two board games, with prime sets A and A', respectively, and let  $\sigma$  and  $\sigma'$  be (not necessarily distinct) players in  $\mathcal{B}$  and  $\mathcal{B}'$ , respectively. Whenever  $a \in A$  and  $a' \in A'$  are related via some  $(\sigma, \sigma')$ -game bisimulation Z, we have

$$a \in \operatorname{Win}_{\sigma}(\mathcal{B})$$
 iff  $a' \in \operatorname{Win}_{\sigma'}(\mathcal{B}')$ .

**Proof.** (Sketch) Without loss of generality we may assume that  $\sigma = \sigma' = 0$ . Let  $a \in A$  and  $a' \in A'$  be such that  $(a, a') \in Z$ , and assume that  $a \in Win_0(\mathcal{B})$ . That is, 0 has a winning strategy f in the initialized game  $\mathcal{B}@a$ . We will use this strategy to provide her with a winning strategy f' in the game  $\mathcal{B}'@a'$ .

The key idea here is that 0 will make sure that any f'-guided  $\mathcal{B}'$ -match is linked to an f-guided  $\mathcal{B}$ -match  $\pi$  through the game bisimulation Z. This is completely analogous to the shadow matches discussed earlier on, the main difference being that now, 0 will only be able to maintain the right link *round by round*, not necessarily move by move.

Call a finite  $\mathcal{B}'$ -match  $\pi'$  safe if  $\mathsf{last}(\pi') \in A'$  and there is an f-guided  $\mathcal{B}$ -match  $\pi$  such that  $\mathsf{last}(\pi) \in A$  and  $(\pi_A, \pi'_{A'}) \in \widetilde{Z}$ . In this case we say that  $\pi$  witnesses the safety of  $\pi'$ . Note that this means in particular that  $(\mathsf{last}(\pi), \mathsf{last}(\pi')) \in Z$ . The main claim in the proof is the following.

CLAIM 1 Let  $\pi'$  be a safe  $\mathcal{B}'$ -match, as witnessed by the *f*-guided  $\mathcal{B}$ -match  $\pi$ . Write  $b := \mathsf{last}(\pi)$ ,  $b' := \mathsf{last}(\pi')$ . Then player 0 has a neigbourhood strategy  $g'_0$  at b' such that for every neighbourhood strategy  $g'_1$  for 1 at b' either 1 gets stuck, or else the resulting extension  $\pi' \diamond \mathsf{res}(g'_0, g'_1)$  of  $\pi'$  is safe, witnessed by an *f*-guided extension  $\rho$  of  $\pi$ .

PROOF OF CLAIM Note that the continuation of player 0's winning strategy f at the match  $\pi$  induces a neighbourhood strategy  $\hat{f}$  for 0, given by  $\hat{f}(\rho) := f(\pi \diamond \rho)$ . Since f is winning for 0 in  $\mathcal{B}@a$ ,  $\hat{f}$  must be at least surviving for her in  $\mathcal{B}^a$ .

Hence Proposition 5.60  $\hat{f}$  induces a set  $X_{\hat{f}} \in P_0(b)$ . But then by definition of a game bisimulation there is a set  $W' \in P_0^{\mathcal{B}'}(b')$  such that  $(W, W') \in \overleftarrow{\wp}(Z)$ . Using Proposition 5.60 once more, we find a surviving neighbourhood strategy  $g'_0$  in  $\mathcal{B}'^{b'}$  such that  $W' = X_{g'}$ .

Now let 0 use this strategy against player 1 in a match of the neighbourhood match  $\mathcal{B}'^{b'}$ . Since g' is surviving, 0 cannot get stuck. In case player 1 gets stuck we are done, so assume otherwise. Where  $g'_1$  is the neighbourhood strategy employed by player 1, we let  $\tau' := \operatorname{res}(g'_0, g'_1)$  be the resulting neighborhood match. It should then be clear that  $c' := \operatorname{last}(\tau) \in W' \subseteq A'$ .

Since  $(X_{\widehat{f}}, W') \in \overleftarrow{\wp}(Z)$  we may find a position  $c \in X_{\widehat{f}}$  such that  $(c, c') \in Z$ ; but  $c \in X_{\widehat{f}}$  implies the existence of some neighbourhood strategy  $f_1$  for 1 in  $\mathcal{B}^b$  such that  $c = \mathsf{last}(\mathsf{res}(f_0, f_1))$ .

Let  $\tau := \operatorname{res}(f_0, f_1)$  be the corresponding neighbourhood match, then  $c = \operatorname{last}(\tau)$  and so  $\rho := \pi \diamond \tau$  is the required f-guided match extending  $\pi$ .

Finally, we leave it for the reader to make explicit how the claim is used to prove the theorem — this part of the proof is similar to many earlier ones. QED

# Notes

The application of game-theoretic methods in the area of logic and automata theory goes back to work of Büchi. The positional determinacy of parity games was proved independently by Emerson & Jutla [6] and by Mostowski in an unpublished technical report. Our proof of this result is based on Zielonka [24].

# Exercises

**Exercise 5.1 (positional determinacy of reachability games)** Give a direct proof of the positional determinacy of reachability games, that is: prove Theorem 5.22.

**Exercise 5.2 (regular games & finite memory strategies)** A strategy  $\alpha$  for player  $\sigma$  in an infinite game  $\mathcal{B} = \langle B_0, B_1, E, W \rangle$  is a *finite memory strategy* if there exists a finite set M, called the *memory set*, an element  $m_I \in M$  and a map  $(\alpha_1, \alpha_2) : B \times M \to B \times M$  such that for all pairs of sequences  $p_0 \cdots p_k \in B^*$  and  $m_0 \cdots m_k \in M^*$ : if  $m_0 = m_I, p_0 \cdots p_k \in \mathrm{PM}_{\sigma}$  and  $m_{i+1} = \alpha_2(p_i, m_i)$  (for all i < k), then  $\alpha(p_0 \cdots p_k) = \alpha_1(p_k, m_k)$ .

Now let  $\mathcal{B}$  be a regular game.

- (a) Define an parity game which covers  $\mathcal{B}$ , with positions  $B \times M$ , where M is the carrier of a deterministic parity automaton  $\mathbb{M}$  recognizing L.
- (b) Show that each player *i* has a finite memory strategy which is winning for them in  $\mathcal{B}@p$  for every  $p \in Win_i$ .

Exercise 5.3 (closed sets) Prove the properties of closed sets as listed in Proposition 5.26.

**Exercise 5.4 (strengthened cover lemma)** Supply the missing details in the proof of the Strengthed Cover Lemma, Proposition 5.52.

Exercise 5.5 (game bisimulation)

Prove the equivalence of the slow and the fast acceptance game for modal automata using game bisimulations.

**Exercise 5.6 (players' powers)** Let A be a prime set relative to some board game  $\mathcal{B} = (B_0, B_1, E, W)$ , let a be some prime position, and let  $\sigma \in \{0, 1\}$  be a player. Then for any subset  $U \subseteq N(a)$  we have that either  $V \subseteq U$  for some  $V \in P_{\sigma}(a)$  or  $U \cap V = \emptyset$  for some  $V \in P_{\overline{\sigma}}(a)$ . Argue that this can be called a *determinacy* property.

# 6 Parity formulas & model checking

In this chapter we introduce parity formulas — structures that also go under the name of alternating tree automata, and that are closely related to various kinds of modal equation systems. Parity formulas are like ordinary (modal) formulas, with the difference that the underlying structure of a parity formula can be an arbitrary directed graph, not only a tree; and that one adds an explicit priority labelling to this underlying graph, to ensure a well-defined game-theoretical semantics. Parity formulas thus provide an alternative, bound-variable-free way of presenting the modal  $\mu$ -calculus.

The advantage of parity formulas over ordinary ones comes out if one has an interest in computational aspects of the modal  $\mu$ -calculus. At the heart of this algorithmic side lie the *parity games* that were introduced in the previous chapter, and the natural way of looking at evaluation games for the modal  $\mu$ -calculus as parity games is *via* parity formulas. Parity formulas themselves have a completely straightforward connection with parity games, which allows for an unambiguous definition of the most relevant complexity measures of parity formulas. In particular, the *size* of a parity formula is simply defined as the number of vertices of its underlying graph, and its *index* corresponds to the maximal length of some naturally defined alternating chain of states.

This algorithmic transparency makes parity formulas very suitable as *yardsticks* for comparing various complexity measures of ordinary  $\mu$ -calculus formulas. Taking this approach, we can further develop the complexity-theoretical framework of the  $\mu$ -calculus by investigating the links between  $\mu$ -calculus formulas and their representation as parity formulas. As an example we mention the analysis of the alternation depth of a formula that we undertake in Section 6.5.

In short, parity formulas are graph-based modal formulas with an added parity condition, that will allow us to view the evaluation games of  $\mu$ -calculus formulas as instances of parity games. Providing a link between the world of  $\mu$ -calculus formulas and that of parity games, they illuminate the complexity-theoretic analysis of various problems related to the modal  $\mu$ -calculus, in particular model checking.

Parity formulas can also be studied in their own right, as an interesting generalisation of the ordinary (tree-based)  $\mu$ -calculus formulas.

# 6.1 Parity formulas

We start with the basic definition of a parity formula. Recall that, given a set P of proposition letters, we define the sets Lit(P) and At(P) of *literals* and *atomic formulas* over P by setting Lit(P) :=  $\{p, \overline{p} \mid p \in \mathsf{P}\}$  and At(P) := Lit(P)  $\cup \{\top, \bot\}$ , respectively.

**Definition 6.1** Let P be a finite set of proposition letters. A parity formula over P is a quintuple  $\mathbb{G} = (V, E, L, \Omega, v_I)$ , where

a) (V, E) is a finite, directed graph, with  $|E[v]| \leq 2$  for every vertex v;<sup>4</sup>

b)  $L: V \to \mathsf{At}(\mathsf{P}) \cup \{\land, \lor, \diamondsuit, \Box, \varepsilon\}$  is a labelling function;

<sup>&</sup>lt;sup>4</sup>When discussing *disjunctive* parity formulas we will drop this requirement, allowing E[v] to be of arbitrary finite size.

c)  $\Omega: V \xrightarrow{\circ} \omega$  is a partial map, the *priority* map of  $\mathbb{G}$ ; and

d)  $v_I$  is a vertex in V, referred to as the *initial* node of  $\mathbb{G}$ ; such that

1) |E[v]| = 0 if  $L(v) \in At(\mathsf{P})$ , and |E[v]| = 1 if  $L(v) \in \{\diamondsuit, \Box\} \cup \{\varepsilon\}$ ;

2) every cycle of (V, E) contains at least one node in  $\mathsf{Dom}(\Omega)$ .

A node  $v \in V$  is called *silent* if  $L(v) = \varepsilon$ , *constant* if  $L(v) \in \{\top, \bot\}$ , *literal* if  $L(v) \in Lit(\mathsf{P})$ , *atomic* if it is either constant or literal, *boolean* if  $L(v) \in \{\land, \lor\}$ , and *modal* if  $L(v) \in \{\diamondsuit, \Box\}$ . We say that a proposition letter q occurs in  $\mathbb{G}$  if  $L(v) \in \{q, \overline{q}\}$  for some  $v \in V$ .

Elements of  $\mathsf{Dom}(\Omega)$  will be called *states*, and we refer to (V, E) as the *(underlying) graph* of the parity formula. A parity formula  $\mathbb{G} = (V, E, L, \Omega, v_I)$  is *balanced* if its states coincide with its silent nodes, that is, if  $\mathsf{Dom}(\Omega) = \{v \in V \mid L(v) = \varepsilon\}$ .

**Remark 6.2** Parity formulas share many characteristics of *automata*, and indeed they also go under the name of *alternating tree automata*. We will say a bit more about this at the end of this section. Since we decided to use the term 'formulas' to describe the objects in Definition 6.1, it will be useful to have an adjective to describe the 'regular' formulas, that is, the elements of the language  $\mu$ ML. We will refer to these as 'ordinary' formulas.

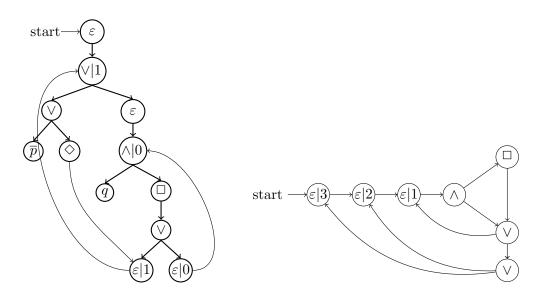

Figure 8: Two parity formulas

**Example 6.3** In Figure 8 we give two examples of parity formulas. The picture on the left displays a parity formula that is directly based on the  $\mu$ -calculus formula  $\xi = \mu x.(\bar{p} \lor \diamondsuit x) \lor \nu y.(q \land \Box(x \lor y))$ , by adding *back edges* to the subformula dag of  $\xi$ . The picture on the right displays a parity formula that is based on the closure graph of the formula  $\xi_1$  of Example 2.38. In both cases we display the label and (if defined) the priority of a node inside its representing circle. Note that the parity formula to the right is balanced, but the one to the left is not.

Position		Player	Admissible moves

(v,s)	with $L(v) = \overline{p}$ and $s \in V(p)$	Ξ	Ø
(v,s)	with $L(v) = \overline{p}$ and $s \notin V(p)$	$\forall$	Ø
(v,s)	with $L(v) = \bot$	Э	Ø
(v,s)	with $L(v) = \top$	$\forall$	Ø
(v,s)	with $L(v) = \varepsilon$	-	$E[v] \times \{s\}$
(v,s)	with $L(v) = \lor$	Э	$E[v] \times \{s\}$
(v,s)	with $L(v) = \wedge$	$\forall$	$E[v] \times \{s\}$
(v,s)	with $L(v) = \diamondsuit$	Ξ	$E[v] \times R[s]$
(v,s)	with $L(v) = \Box$	$\forall$	$E[v] \times R[s]$

Table 9: The evaluation game  $\mathcal{E}(\mathbb{G},\mathbb{S})$ 

The definition of parity formulas needs little explanation. Condition 2) says that every cycle must pass through at least one state; this is needed to provide a winner for infinite matches of the evaluation games that we use to define the semantics of parity formulas. The rules (admissible moves) in this evaluation game are completely obvious.

**Definition 6.4** Let  $\mathbb{S} = (S, R, V)$  be a Kripke model for a set P of proposition letters, and let  $\mathbb{G} = (V, E, L, \Omega, v_I)$  be a parity P-formula. The *evaluation game*  $\mathcal{E}(\mathbb{G}, \mathbb{S})$  is the parity game  $(G, E', \Omega')$  of which the board consists of the set  $V \times S$ , the priority map  $\Omega' : V \times S \to \omega$  is given by

$$\Omega'(v,s) := \begin{cases} \Omega(v) & \text{if } v \in \mathsf{Dom}(\Omega) \\ 0 & \text{otherwise,} \end{cases}$$

and the game graph is given in Table 8. Note that we do not need to assign a player to positions that admit a single move only.  $\lhd$ 

**Definition 6.5** We say that a parity formula  $\mathbb{G} = (V, E, L, \Omega, v_I)$  holds at or is satisfied by a pointed Kripke model  $(\mathbb{S}, s)$ , notation:  $\mathbb{S}, s \Vdash \mathbb{G}$ , if the pair  $(v_I, s)$  is a winning position for  $\exists$  in  $\mathcal{E}(\mathbb{G}, \mathbb{S})$ . Analogously to ordinary formulas, we define the *meaning* of a parity formula  $\mathbb{G}$ in a Kripke model  $\mathbb{S}$  as follows:

$$\llbracket \mathbb{G} \rrbracket^{\mathbb{S}} := \{ s \in S \mid \mathbb{S}, s \Vdash \mathbb{G} \},\$$

and, for any propositional variable x, the map  $\mathbb{G}_x^{\mathbb{S}} : \wp(S) \to \wp(S)$  by setting

$$\mathbb{G}_x^{\mathbb{S}}(A) := \llbracket \mathbb{G} \rrbracket^{\mathbb{S}[x \mapsto A]}$$

We call two parity formulas  $\mathbb{G}$  and  $\mathbb{G}'$  equivalent if they have the same meaning in any model, notation:  $\mathbb{G} \equiv \mathbb{G}'$ . We will use the same terminology and notation to compare parity formulas with standard formulas.

The two key complexity measures of a parity formula, viz., size and index, both have perspicuous definitions. We will introduce these measures here, together some other useful notions pertaining to parity formulas.

**Definition 6.6** The *size* of a parity formula  $\mathbb{G} = (V, E, L, \Omega, v_I)$  is defined as its number of nodes:  $|\mathbb{G}| := |V|$ .

Next to size, as the second fundamental complexity measure for a parity formula we need is its *index*, which corresponds to the alternation depth of ordinary formulas. It concerns the degree of alternation between odd and even positions in an infinite match of the evaluation game, and it is thus closely related to the range of the priority map of the formula. The most straightforward approach would be to define the index of a parity formula as the size of this range; a slightly more sophisticated approach is a *clusterwise* version of this.

**Definition 6.7** Let  $\mathbb{G} = (V, E, L, \Omega, v_I)$  be a parity formula, and let u and v be vertices in V. We say that v is *active* in u if  $E^+uv$ , and we let  $\bowtie_E \subseteq V \times V$  hold between u and v is u is active in v and vice versa, i.e.,  $\bowtie_E := E^+ \cap (E^{-1})^+$ . We let  $\equiv_E$  be the equivalence relation generated by  $\bowtie_E$ ; the equivalence classes of  $\equiv_E$  will be called *clusters*. A cluster C is called *transient* if it is a singleton  $\{v\}$  such that v is not active in itself, and *proper* otherwise.

The collection of clusters of a parity formula  $\mathbb{G}$  is denoted as  $Clus(\mathbb{G})$ , and we say that a cluster C is *higher* than another cluster C' if there are some  $u \in C$  and  $u \in C'$  with  $E^+uu'$ .

Note that a cluster is transient iff there is a nontrivial path between any pair of vertices. Intuitively, vertices belong to the same (proper) cluster if they can jointly occur infinitely often in some infinite match of some acceptance game for the formula. Furthermore, note that the notion of one cluster being higher than another could have been defined in many different (but equivalent) ways. For instance, C is higher than C' iff for every  $u \in C$  there is a  $u' \in C'$  with  $E^+uu'$ , iff  $E^+uu'$  holds for every  $u \in C$  and  $u' \in C$ , etc. Finally, observe that the 'higher than' relation between clusters is a partial order.

**Proposition 6.8** Let  $\tau = (t_n)_{n \in \omega}$  be an infinite path through the graph of a parity formula  $\mathbb{G}$ . Then  $\mathbb{G}$  has a unique cluster C such that, for some k, all  $t_n$  with n > k belong to C. This cluster is proper.

As a corollary of this, the relative priorities of states only matter if we stay in the same cluster.

**Definition 6.9** Let  $\mathbb{G} = (V, E, L, \Omega, v_I)$  be a parity formula. Given a cluster C of  $\mathbb{G}$ , we define its *index* as the number of priorities reached by states in C, that is,  $ind_{\mathbb{G}}(C) = |\mathsf{Ran}(\Omega|_C)|$ . The *index of*  $\mathbb{G}$  is given as the maximal index of its proper clusters,  $ind(\mathbb{G}) := \max\{ind_{\mathbb{G}}(C) \mid C \in Clus(\mathbb{G}) \text{ proper}\}.$ 

Note that a proper cluster must have at least one state. Consequently, a parity formula has a nonzero index iff it has proper clusters.

The notion of balance comes into the picture when we consider the operations of transforming ordinary formulas into parity formulas and vice versa. The following proposition, the proof of which is left to the reader, will then become important.

**Proposition 6.10** Let  $\mathbb{G}$  be a parity formula. Then there is an equivalent balanced parity formula  $\mathbb{G}'$  of size  $|\mathbb{G}'| \leq 2 \cdot |\mathbb{G}|$  and index  $ind(\mathbb{G}') = ind(\mathbb{G})$ .

### Alternative presentation: alternating tree automata and equation systems

As mentioned earlier, in the literature one may find our parity formulas (or very similar structures) under the names of *alternating tree automata* or *(hierarchical or modal) equation systems*. We discuss these alternative perspectives here.

An alternating tree automaton or ATA over a set  $\mathsf{P}$  of proposition letters is a quadruple  $\mathbb{A} = (A, \Theta, \Omega, a_I)$ , where A is a finite set of objects called *states*,  $a_I \in A$  is an element of A called the *initial state*,  $\Omega : A \to \omega$  is a (total) priority function, and  $\Theta : A \to \mathsf{TC}(\mathsf{P}, A)$  is the *transition map* of the automaton. Here  $\mathsf{TC}(\mathsf{P}, A)$  is a logical language of usually rather simple modal formulas that are called *transition conditions* over ( $\mathsf{P}$  and) A. The exact definition of this language comes with some variations; here we define the set  $\mathsf{TC}(\mathsf{P}, A)$  via the following grammar:

 $\alpha ::= \bot \mid \top \mid p \mid \overline{p} \mid a \mid \diamond a \mid \Box a \mid a \land b \mid a \lor b, \tag{60}$ 

where  $p \in \mathsf{P}$  and  $a, b \in A$ .

The (operational) semantics of alternating tree automata is formulated in terms of an acceptance game  $\mathcal{A}(\mathbb{A}, \mathbb{S})$ , for an ATA  $\mathbb{A}$  and a Kripke model  $\mathbb{S} = (S, R, V)$ . The positions of this game are given as the set

$$\{(\alpha, s) \in A \times S \mid a \in A \text{ or } \alpha = \Theta(a), \text{ for some } a \in A\},\$$

while its rules and winning conditions are listed in Table 9.

Position		Player	Admissible moves
(a,s)	with $\Theta(a) = \bot$	Ξ	Ø
(a,s)	with $\Theta(a) = \top$	$\forall$	Ø
(a,s)	with $\Theta(a) = p$ and $s \in V(p)$	$\forall$	Ø
(a,s)	with $\Theta(a) = p$ and $s \notin V(p)$	Э	Ø
(a,s)	with $\Theta(a) = \neg p$ and $s \in V(p)$	Ξ	Ø
(a,s)	with $\Theta(a) = \neg p$ and $s \notin V(p)$	$\forall$	Ø
(a,s)	with $\Theta(a) = b$	-	$\{(b,s)\}$
(a,s)	with $\Theta(a) = (b_0 \vee b_1)$	Э	$\{(b_0, s), (b_1, s)\}$
(a,s)	with $\Theta(a) = (b_0 \wedge b_1)$	$\forall$	$\{(b_0, s), (b_1, s)\}$
(a,s)	with $\Theta(a) = \diamondsuit b$	Э	$\{(a,t) \mid sRt\}$
(a,s)	with $\Theta(a) = \Box b$	$\forall$	$\{(a,t) \mid sRt\}$

Table 10: The acceptance game  $\mathcal{A}(\mathbb{A}, \mathbb{S})$ 

From this definition it is fairly obvious that we may identify parity formulas and ATAS: with an alternating tree automaton  $\mathbb{A}$  we may associate the parity formula  $\mathbb{G}_{\mathbb{A}} = (A, E, L, \Omega, a_I)$ given by

$$E(a) := \begin{cases} \varnothing & \text{if } \Theta(a) \in \operatorname{At}(\mathsf{P}) \\ \{b\} & \text{and} & L(a) := \begin{cases} \Theta(a) & \text{if } \Theta(a) \in \operatorname{At}(\mathsf{P}) \\ \varepsilon & \text{if } \Theta(a) = b, \text{ for some } b \in A \\ \heartsuit & \text{if } \Theta(a) = \heartsuit b, \text{ for some } b \in A \\ \odot & \text{if } \Theta(a) = a_0 \odot a_1, \text{ for some } a_0, a_1 \in A \end{cases}$$

Conversely, it is equally simple to turn a parity formula into an alternating tree automaton which is based on the set of vertices of the formula. Note that if we simply take the size of an automaton to be its number of states, the constructions that we just outlined respect size in either direction.

Another perspective on alternating tree automata is that of *hierarchical equation systems* or HESS. We need not go into detail here, but to get the basic idea, fix an ATA  $\mathbb{A} = (A, \Theta, \Omega, a_I)$ . Think of the states in A as *variables*, then with each state  $a \in A$  we may associate an *equation* of the form  $a = \Theta(a)$ , and make this equation inherit the priority  $\Omega(a)$ . Then we may organise this collection of equations by grouping equations of the same priority together in so-called *blocks*, and order these blocks according to their priorities. The result of this operation is known as a hierarchical equation system. It should be clear from this description that there is a 1-1 correspondence between alternating tree automata and these hierarchical equations systems.

Finally, the definition of HESS and ATAS can be modified/generalised in two directions. First of all, one may vary the set of admissible transition conditions. For instance, a so-called *modal equation system* or MES corresponds to an alternating tree automaton  $\mathbb{A} = (A, \Theta, \Omega, a_I)$  where the transition map  $\Theta$  maps every state  $a \in A$  to an arbitrary modal formula as given by the following grammar

$$\alpha, \beta ::= \bot \mid \top \mid p \mid \overline{p} \mid a \mid \Diamond \alpha \mid \Box \alpha \mid \alpha \land \beta \mid \alpha \lor \beta, \tag{61}$$

where  $p \in \mathsf{P}$  and  $a \in A$ . The acceptance game associated with these automata are obtained via a minor modification of the one given in Table 9. Note, however, that in this case one should not simply take the size of the ATA to be its number of states; one has to take the size of the formulas in the range of the transition map into account as well.

Second, one may change the nature of the transition map so that it shifts the propositions from its output (transition conditions) to the input. That is, given a finite set P of proposition letters, think of its power set  $\wp P$  as an alphabet of *colours*. The transition map of an ATA can then be given as a map  $\Theta : A \times \wp P \to TC(A)$  mapping pairs of states and colours to transition conditions that now may only involve the states of the automata as propositional variables. The resulting *modal* automata will be discussed in detail in Chapter 10.

### Exercises

**Exercise 6.1** Provide an effective procedure transforming an arbitrary parity formula  $\mathbb{G}$  into an equivalent balanced parity formula  $\mathbb{G}^b$  such that  $|\mathbb{G}^b| \leq 2 \cdot |\mathbb{G}|$  and  $ind(\mathbb{G}^b) = ind(\mathbb{G})$ .

## 6.2 Basics

# Model checking for parity formulas

Since the evaluation game for parity formulas is given as a parity game, we immediately get a quasi-polynomial upper bound on the time complexity of the *model checking* problem for parity formulas. Recall that the size of a (pointed) labelled transition system is simply defined as the number of points in the model.

**Definition 6.11** The model checking problem for parity formulas is the problem to compute whether  $\mathbb{S}, s \Vdash \mathbb{G}$ , where  $\mathbb{S}$  is a (finite) labelled transition system, and  $\mathbb{G}$  is a parity formula.  $\triangleleft$ 

**Theorem 6.12** Assume that the problem of determining the winning regions of a parity game  $\mathbb{G}$  can be solved in time f(n,d), where n and d are, respectively, the size and the index of  $\mathbb{G}$ . Then the model checking problem for parity formulas can be solved in time  $f(m \cdot n, d + 1)$ , where m is the size of the labelled transition system, and n and d are the size and index of the parity formula, respectively.

**Remark 6.13** In the above theorem we state the model checking problem as being solvable in time  $f(m \cdot n, d + 1)$ , and not  $f(m \cdot n, d)$ . The reason for adding the '+1' is a technicality: the index of a parity game is usually defined as the *global* range of the priority map, whereas for parity formulas we define the index as the *clusterwise* size of the priority map. This makes a difference of 1 in the case of a parity formula of index d which has a cluster C with  $\mathsf{Ran}(\Omega \upharpoonright_C) = \{0, \ldots, d-1\}$  and another cluster C' with  $\mathsf{Ran}(\Omega \upharpoonright_{C'}) = \{1, \ldots, d\}$ .

In the next section we will see how we can use this result to analyse the computational complexity of the model checking problem for ordinary formulas.

## **Operations on parity formulas**

Parity formulas are interesting logical objects in their own right, and so one might want to develop their theory. To start with, it is fairly easy to define various operations on parity formulas. The following proposition covers the boolean operations (including negation), the modalities, and substitution.

**Proposition 6.14** Let  $\mathbb{G} = (V, E, L, \Omega, v_I)$  and  $\mathbb{G} = (V', E', L', \Omega', v'_I)$  be two parity formulas.

1) There is a parity formula  $\mathbb{H}$  such that  $|\mathbb{H}| \leq 1 + |\mathbb{G}| + |\mathbb{G}'|$  and  $ind(\mathbb{H}) \leq max(ind(\mathbb{G}), ind(\mathbb{G}'))$ , while for any pointed Kripke model  $(\mathbb{S}, s)$  we have

$$\mathbb{S}, s \Vdash \mathbb{H} \text{ iff } \mathbb{S}, s \Vdash \mathbb{G} \text{ and } \mathbb{S}, s \Vdash \mathbb{G}'.$$

2) There is a parity formula  $\mathbb{H}$  such that  $|\mathbb{H}| \leq 1 + |\mathbb{G}| + |\mathbb{G}'|$  and  $ind(\mathbb{H}) \leq max(ind(\mathbb{G}), ind(\mathbb{G}'))$ , while for any pointed Kripke model  $(\mathbb{S}, s)$  we have

$$\mathbb{S}, s \Vdash \mathbb{H} \ iff \mathbb{S}, s \Vdash \mathbb{G} \ or \mathbb{S}, s \Vdash \mathbb{G}.$$

3) There is a parity formula  $\mathbb{H}$  such that  $|\mathbb{H}| = |\mathbb{G}|$  and  $ind(\mathbb{H}) \leq ind(\mathbb{G})$ , while for any pointed Kripke model  $(\mathbb{S}, s)$  we have

$$\mathbb{S}, s \Vdash \mathbb{H} \ iff \ \mathbb{S}, s \not\models \mathbb{G}.$$

4) There is a parity formula  $\mathbb{H}$  such that  $|\mathbb{H}| \leq 1 + |\mathbb{G}|$  and  $ind(\mathbb{H}) \leq ind(\mathbb{G})$ , while for any pointed Kripke model  $(\mathbb{S}, s)$  we have

 $\mathbb{S}, s \Vdash \mathbb{H} \text{ iff } \mathbb{S}, t \Vdash \mathbb{G} \text{ for some } t \in R[s].$ 

5) There is a parity formula  $\mathbb{H}$  such that  $|\mathbb{H}| \leq 1 + |\mathbb{G}|$  and  $ind(\mathbb{H}) \leq ind(\mathbb{G})$ , while for any pointed Kripke model  $(\mathbb{S}, s)$  we have

 $\mathbb{S}, s \Vdash \mathbb{H} \text{ iff } \mathbb{S}, t \Vdash \mathbb{G} \text{ for all } t \in R[s].$ 

6) There is a parity formula  $\mathbb{H}$  such that  $|\mathbb{H}| \leq |\mathbb{G}| + |\mathbb{G}'|$  and  $ind(\mathbb{H}) \leq max(ind(\mathbb{G}), ind(\mathbb{G}'))$ , while for any pointed Kripke model  $(\mathbb{S}, s)$  we have

$$\mathbb{S}, s \Vdash \mathbb{H} \ iff \ \mathbb{S}[x \mapsto [\mathbb{G}']^{\mathbb{S}}], s \Vdash \mathbb{G}.$$

**Proof.** We only cover the case of conjunctions, leaving the other cases as exercises to the reader. Given the parity formulas  $\mathbb{G}$  and  $\mathbb{G}$ , we let  $\mathbb{G} \wedge \mathbb{G}' := (V'', E'', L'', \Omega'', v_I')$  be the structure given as follows. We let V'' be the disjoint union of V, V' and some singleton  $\{v''\}$ , and we define  $E'' := E \cup E' \cup \{(v'', v_I), (v'', v_I')\}$ . Furthermore we put  $L''(v'') := \wedge$ , while we let L'' agree with L on V and with L' on V'. Similarly, we leave  $\Omega''$  undefined on v'' and let  $\Omega''$  agree with  $\Omega$  on V and with  $\Omega'$  on V'. Finally, we define  $v_I'' := v''$ . It is then completely straightforward to show that  $\mathbb{G} \wedge \mathbb{G}'$  is a parity formula indeed, and that it is equivalent to the conjunction of  $\mathbb{G}$  and  $\mathbb{G}'$ . QED

The proposition below covers the least and greatest fixpoint operation. We leave its proof as an exercise for the reader.

**Proposition 6.15** Let  $\mathbb{G} = (V, E, L, \Omega, v_I)$  be a parity formula, and let x be a proposition letter that only occurs positively in  $\mathbb{G}$ . Then the following hold:

- 1) The map  $\mathbb{G}_x^{\mathbb{S}}: \wp(S) \to \wp(S)$  is monotone, for any Kripke model based on S.
- 2) There is a parity formula  $\mathbb{H}$  such that  $|\mathbb{H}| \leq |\mathbb{G}|$  and  $ind(\mathbb{H}) \leq ind(\mathbb{G})$ , while for any Kripke model  $\mathbb{S}$  we have

$$\llbracket \mathbb{H} \rrbracket^{\mathbb{S}} = \mathrm{LFP}.\mathbb{G}_x^{\mathbb{S}}.$$

3) There is a parity formula  $\mathbb{H}$  such that  $|\mathbb{H}| \leq |\mathbb{G}|$  and  $ind(\mathbb{H}) \leq ind(\mathbb{G})$ , while for any Kripke model  $\mathbb{S}$  we have

$$\llbracket \mathbb{H} \rrbracket^{\mathbb{S}} = \mathrm{GFP.} \mathbb{G}_x^{\mathbb{S}}$$

Lectures on the modal  $\mu$ -calculus

## Morphisms and equivalence notions between parity formulas

Furthermore, we will need various *structural* notions of equivalence between parity formulas. A simple but very useful concept is that of two parity formulas being *parity variants*.

**Definition 6.16** A parity variant of a parity formula  $\mathbb{G} = (V, E, L, \Omega, v_I)$  is a parity formula  $\mathbb{G} = (V, E, L, \Omega', v_I)$  such that (i)  $\Omega(v) \equiv_2 \Omega'(v)$ , for all v, and (ii)  $\Omega(u) < \Omega(v)$  iff  $\Omega'(u) < \Omega'(v)$ , for all u and v that belong to the same cluster but have different parity.

It is easy to see that parity variants are semantically equivalent, and have the same size (but not necessarily the same index). From this it follows that there are certain normal forms for parity formulas. Recall that we define  $[k, n] := \{i \in \omega \mid k \leq i \leq n\}$ .

**Definition 6.17** A parity formula  $\mathbb{G} = (V, E, L, \Omega, v_I)$  is called *lean* if  $\Omega$  is injective, and *tight* if for any cluster C, the range of  $\Omega$  on C is connected, that is, of the form  $\mathsf{Ran}(\Omega \upharpoonright_C) = [k, n]$  for some natural numbers k, n with  $k \leq n$ .

It is not hard to see that every parity formula can be effectively transformed into either a lean or a tight parity variant.

Turning to the notion of a *morphism* between parity formulas, we have various options. Given the coalgebraic flavour of parity formula, it should come as no surprise that the definition we take integrates elements of the notion of a bounded morphism between Kripke models. The definition also incorporates the notion of a parity variant of Definition 6.16.

**Definition 6.18** Let  $\mathbb{G} = (V, E, L, \Omega, v_I)$  and  $\mathbb{G}' = (V', E', L', \Omega', v'_I)$  be two parity formulas. A *morphism* from  $\mathbb{G}$  to  $\mathbb{G}'$  is a map  $f : V \to V'$  satisfying the following conditions, for all  $u, v \in V$ :

- 1) L(u) = L'(f(u))
- 2) if Euv then E'f(u)f(v)
- 3) if E'f(u)v' then Euv for some v with f(v) = v'
- 4) (a)  $\Omega(v) \equiv_2 \Omega'(fv)$ , for all v, and (b)  $\Omega(u) < \Omega(v)$  iff  $\Omega'(fu) < \Omega'(fv)$ , for all u and v that belong to the same cluster but have different parity
- 5)  $f(v_I) = v'_I$ .

We write  $f : \mathbb{G} \to \mathbb{G}'$  to denote that f is a surjective morphism from  $\mathbb{G}$  to  $\mathbb{G}'$ .

As an example, here is the parity formula version of a subformula.

**Definition 6.19** Let  $\mathbb{G} = (V, E, L, \Omega, v_I)$  be a parity formula, and let v be a vertex in V. We let  $\mathbb{G}\langle v \rangle := (V, E, L, \Omega, v)$  denote the variant of  $\mathbb{G}$  that takes v as its initial node; we define  $V_v$  to be the smallest subset of V which contains v and is closed under taking successors, and we call  $\mathbb{G}_v := (V_v, E \upharpoonright_{V_v}, L \upharpoonright_{V_v}, \Omega \upharpoonright_{V_v}, v)$  the subformula of  $\mathbb{G}$  that is generated from v.

The following proposition will be needed further on; we omit its proof, since it is straightforward. **Proposition 6.20** Let  $f : \mathbb{G} \to \mathbb{G}'$  be a morphism of parity formulas. Then for any node v in  $\mathbb{G}$  it holds that

$$\mathbb{G}\langle v\rangle \equiv \mathbb{G}'\langle f(v)\rangle.$$

In particular, for every node  $v \in V$  we have

 $\mathbb{G}\langle v\rangle \equiv \mathbb{G}_v.$ 

In the same way that one may generalize bounded morphisms to bisimulations, we can generalize parity formula morphisms to parity formula bisimulations.

**Definition 6.21** Let  $\mathbb{G} = (V, E, L, \Omega, v_I)$  and  $\mathbb{G}' = (V', E', L', \Omega', v'_I)$  be two parity formulas. A parity formula bisimulation between  $\mathbb{G}$  and  $\mathbb{G}'$  is a relation  $Z \subseteq V \times V'$  satisfying the following conditions, for all  $u, v \in V$  and  $u', v' \in V'$  such that  $(u, u'), (v, v') \in Z$ :

- 1) L(u) = L'(f(u))
- 2) if Euv then there is some  $w' \in V'$  such that  $(v, w') \in Z$  and Eu'w';
- 3) if E'u'v' then there is some  $w \in V$  such that  $(w, v') \in Z$  and Euw;
- 4) (a)  $\Omega(u) \equiv_2 \Omega'(u')$  and (b)  $\Omega(u) < \Omega(v)$  iff  $\Omega'(u') < \Omega'(v')$ , if u and v in  $\mathbb{G}$ , and u' and v' in  $\mathbb{G}'$  belong to the same cluster but have different parity;
- 5)  $(v_I, v'_I) \in Z$ .

We write  $Z: \mathbb{G} \sim \mathbb{G}'$  to denote that Z is a parity formula bisimulation between  $\mathbb{G}$  and  $\mathbb{G}'$ .

**Proposition 6.22** Let  $Z : \mathbb{G} \sim \mathbb{G}'$  be a parity formula bisimulation. Then we have

 $\mathbb{G}\langle v \rangle \equiv \mathbb{G}' \langle v' \rangle$ , whenever  $(v, v') \in Z$ .

▶ Somewhere: expansion map is a parity formula morphism;

# 6.3 From ordinary formulas to parity formulas

In this section we will see how to represent a ordinary formula as an equivalent parity formula. In order to use the complexity result for the model checking problem for parity formulas to make similar observations on the model checking of ordinary formulas, we obviously want to minimize the *size* and the *index* of the representation. It should come as no surprise that the index of this parity formula will somehow correspond to the alternation depth of the formula, while the size of the parity formula will clearly depend on the graph structure that we pick to represent the original formula.

Suppose that we are looking for a parity formula  $\mathbb{G} = (V, E, L, \Omega, v_I)$  representing the ordinary formula  $\xi$ . It seems that there are three natural candidates for the underlying graph (V, E) of  $\mathbb{G}$ : we could take the syntax tree of  $\xi$ , its subformula graph, or its closure graph. Note that each of these three structures induces a natural *size measure* of  $\mu$ -calculus formulas, respectively length, subformula-size, and (closure-)size. The tree representation has the advantage of being immediately available for any  $\xi \in \mu$ ML, whereas the subformula and closure graph are defined only for the clean and the tidy formulas, respectively. Because of the unwieldy size of syntax trees, however, we focus here on the other two kinds of representations.

**Definition 6.23** The subformula dag of a clean formula  $\xi$  is the graph  $(Sf(\xi), \triangleright_0)$ , where  $\triangleright_0$  is the converse of the direct subformula relation  $\triangleleft_0$ . We obtain the subformula graph  $(Sf(\xi), \triangleright_0 \cup B)$  from this by adding the set  $B := \{(x, \delta_x) \mid x \in BV(\xi)\}$  of back edges to this dag. The closure graph of a tidy formula  $\xi \in \mu$ ML is the structure  $\mathbb{C}_{\xi} = (Cl(\xi), \rightarrow_C)$ , where  $\rightarrow_C$  is the trace relation (restricted to the closure of  $\xi$ ).

In the remainder of this section we will see how to expand either of these two graphs into a full parity formula structure. In both cases it is obvious how to define the labelling map L, and which vertex to take as the initial one. It is also more or less clear what the *states* should be, i.e., on which vertices the priority map  $\Omega$  should be defined: In the case of the subformula graph of a clean formula  $\xi$  we will take the set  $BV(\xi)$  of *bound variables* of  $\xi$ , while in the closure graph of a tidy formula  $\xi$  we will consider the set of all *fixpoint formulas* in the closure of  $\xi$ .

For the actual values of the priority maps, there is some choice. Observe, however, that in both versions of the evaluation game, the winning conditions are defined in terms of some priority order on the set of states, in combination with a fixed assignment of a parity/player to each state. For instance, in the case of the subformula game for a clean formula  $\xi$ , we used the unfolding order  $\leq_{\xi}$  on  $BV(\xi)$ , together with the partition of  $BV(\xi)$  into  $\mu$ - and  $\nu$ -variables. To assign a winner to an infinite match  $\pi$ , we consider the  $\leq_{\xi}$ -maximal element of the set  $Unf^{\infty}(\pi)$  (consisting of those bound variables that are unfolded infinitely often during  $\pi$ ), and the winner of  $\pi$  is then determined by the nature of this variable. Similarly, in the case of the closure game for  $\xi$ , we looked at the fixpoint formulas that occur infinitely often in an infinite match of the game, and observed that this set has a smallest element with respect to the (free) subformula ordering.

It therefore makes sense to discuss how to transform a priority order on the set of states into a suitable priority map, *in some generality*. Playing with the shape of the priority order may have an effect on the *index* of the associated priority map, and one priority order may yield a lower index than another. Interestingly, both for the subformula game and for the closure game, we will see that the order used in Chapter 2 does *not* give an optimal index.

# 6.3.1 From parity posets to priority maps

In this subsection we will see how to represent a priority order on some (partitioned) set of states by a suitable priority map. We first develop some terminology. Throughout this subsection the reader should think of Z as the set of states in (some cluster of) a parity formula that is either based on the subformula graph or on the closure graph of a formula  $\xi$ .

**Definition 6.24** A parity poset is a structure  $\mathbb{Z} = (Z, \preccurlyeq, p)$ , where  $(Z, \preccurlyeq)$  is a finite poset and p is a parity map on P, that is, a map  $p : Z \to \{0,1\}$ . We write  $z \prec z'$  if  $z \preccurlyeq z'$  and  $z \neq z'$ .

**Example 6.25** Where  $\xi$  is a clean formula, take  $Z := BV(\xi)$ , and let p be the function mapping  $\mu$ -variables to 1 and  $\nu$ -variables to 0. The most obvious priority order on  $BV(\xi)$  is the relation  $\leq_{\xi}$  given by

$$x \leq \xi y \text{ if } \delta_x \leq \delta_y.$$

For a tidy formula  $\xi$  we may take Z to be the set of fixpoint formulas belonging to  $Cl(\xi)$ , and let p be the function mapping  $\mu$ -formulas to 1 and  $\nu$ -formulas to 0. The most obvious priority order on this set is the relation  $\geq_f$ , that is, the converse of the free subformula relation.

To give a precise formulation of the required connection between parity posets and priority maps, we need the notion of an *alternating chain* in a parity poset, which is a good measure of its complexity.

**Definition 6.26** Let  $\mathbb{Z} = (Z, \preccurlyeq, p)$  be a parity poset. An alternating chain in  $\mathbb{Z}$  of length k in  $\mathbb{Z}$  is a finite sequence  $z_1 \cdots z_k$  of states such that, for all  $i < k, z_i \prec z_{i+1}$  while  $z_i$  and  $z_{i+1}$  have different parity. The alternating chain depth  $\operatorname{acd}(\mathbb{Z})$  of Z is the maximal length of an alternating chain in  $\mathbb{Z}$ .

Since the parity map on a set of states is usually fixed, with a slight abuse of notation we will often write  $\operatorname{acd}(\preccurlyeq)$  rather than  $\operatorname{acd}(Z, \preccurlyeq, p)$ ; this notation is particularly useful if we compare distinct priority relations on a fixed set Z (with a fixed parity map p).

**Definition 6.27** Let  $\mathbb{Z} = (Z, \preccurlyeq, p)$  be a parity poset, and let  $\Omega : Z \to \omega$  be some priority map. Then we say that  $\Omega$  represents  $\mathbb{Z}$  if it satisfies the following conditions, for all  $x, z \in Z$ :

1)  $p(z) = \Omega(z) \mod 2;$ 2)  $x \leq z$  implies  $\Omega(x) \leq \Omega(z).$ 

The conditions 1 and 2 constitute some kind of soundness condition: if  $\Omega$  represents  $\mathbb{Z}$ , then it yields the same winning conditions as  $\mathbb{Z}$ . This is the content of the next Proposition, the proof of which is trivial.

Lectures on the modal  $\mu$ -calculus

**Proposition 6.28** Let  $\mathbb{Z} = (Z, \preccurlyeq, p)$  and  $\Omega : Z \to \omega$  be, respectively, a parity poset and a priority map representing it. Furthermore, let  $\zeta = (z_n)_{n < \omega}$  be an infinite sequence of elements in Z, and assume that the set  $Inf(\zeta)$  has a  $\preccurlyeq$ -greatest element z. Then p(z) = 0 iff  $\max(\Omega[Inf(\zeta)])$  is even.

It is important to keep the range  $\mathsf{Ran}(\Omega)$  of priorities small, given its contribution to the complexity of the model checking of parity formulas. It is not hard to see that the elements of an alternating chain all need to have a different priority, which means that  $\mathsf{acd}(\mathbb{Z})$  is a lower bound for  $|\mathsf{Ran}(\Omega)|$ . The example below shows that in general we cannot even require that  $|\mathsf{Ran}(\Omega)| = \mathsf{acd}(\mathbb{Z})$ :

Where  $\mathbb{Z}$  is the parity preorder in the picture, it is impossible to represent  $\mathbb{Z}$  by a priority map  $\Omega$  with  $|\mathsf{Ran}(\Omega)| = 2$ . However, if we partition  $\mathbb{Z}$  into components and consider the alternating chain depth piecewise, a precise match is possible. For instance, in the case where Z is the closure set of some formula  $\xi$ , one may take the *clusterwise* converse subformula ordering; that is, only rank  $\psi$  higher than  $\varphi$  if ( $\psi$  is a subformula of  $\varphi$  and) there are traces from  $\varphi$  to  $\psi$  and vice versa.

**Definition 6.29** Let  $\mathbb{Z} = (Z, \preccurlyeq, p)$  be a parity poset. A partition  $(Z_i)_{i \in I}$  is called *disconnected* if there are no elements  $z_i, z_j$  in different components such that  $z_i \preccurlyeq z_j$ . In this setting we let  $\mathbb{Z}_i$  denote the substructure of  $\mathbb{Z}$  based on the set  $Z_i$ .

We call a map  $\Omega: \mathbb{Z} \to \omega$  representing  $\mathbb{Z}$  a *tight* representation if  $\mathbb{Z}$  admits a disconnected partition  $(\mathbb{Z}_i)_{i \in I}$  such that  $\operatorname{acd}(\mathbb{Z}_i) = |\operatorname{Ran}(\Omega \upharpoonright_{\mathbb{Z}_i})|$ , for each component  $\mathbb{Z}_i$ .

**Example 6.30** Figure 9 below depicts a parity poset (the picture to the left) and two priority maps representing it; the priority map to the right is tight, the other one is not.  $\triangleleft$ 

The key result here is that, under a mild condition that is met in the relevant cases, every parity poset is indeed tightly represented by some priority map.

**Definition 6.31** We say that  $\mathbb{Z}$  is *weakly directed* if Z admits a disconnected partition consisting of *directed* subsets.

It will be convenient for us to define a *canonical* priority map for this purpose.

**Definition 6.32** Let  $\mathbb{Z} = (Z, \preccurlyeq, p)$  be a parity poset; partition  $\mathbb{Z}$  into maximal connected components, and assume that every component of  $\mathbb{Z}$  has finite alternation depth.

Given a point  $z \in Z$  we define  $h^{\uparrow}(z)$  (respectively,  $h^{\downarrow}(z)$ ) as the maximal length of an alternating chain starting at z (ending at z, respectively). We define the following map  $\Omega_{\mathbb{Z}}: Z \to \omega$ ; given  $z \in Z$ , let  $\mathbb{Z}_z$  be the component to which z belongs, and define

$$\Omega_{\mathbb{Z}}(z) := \begin{cases} \operatorname{acd}(\mathbb{Z}_z) - h^{\uparrow}(z) & \text{if } \operatorname{acd}(\mathbb{Z}_z) - h^{\uparrow}(z) \equiv_2 p(z) \\ \operatorname{acd}(\mathbb{Z}_z) - h^{\uparrow}(v) + 1 & \text{if } \operatorname{acd}(\mathbb{Z}_z) - h^{\uparrow}(z) \not\equiv_2 p(z), \end{cases}$$
(62)

and we will call this map the priority map induced by  $\mathbb{Z}$ .

 $\triangleleft$ 

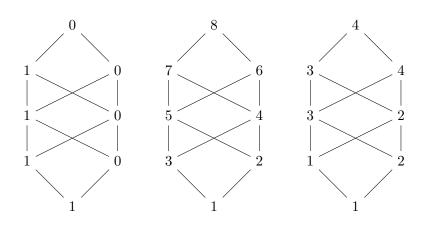

Figure 9: From a parity poset to a priority map

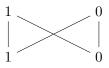

With a minor abuse of notation, we will often denote the priority map  $\Omega_{\mathbb{Z}}$  as  $\Omega_{\preccurlyeq}$ .

**Theorem 6.33** Every weakly directed parity poset  $\mathbb{Z} = (Z, \preccurlyeq, p)$  is tightly represented by its induced priority map  $\Omega_{\mathbb{Z}}$ .

**Proof.** To avoid clutter we write  $\Omega$  for  $\Omega_{\mathbb{Z}}$ . It is not very difficult to see that  $\Omega$  represents  $\mathbb{Z}$ : the parity condition is straightforward, and for the order preservation it suffices to observe that  $x \preccurlyeq y$  implies  $h^{\uparrow}(x) \ge h^{\uparrow}(y)$ , which in its turn implies  $\Omega(x) \le \Omega(y)$ . For tightness, without loss of generally we may assume that  $\mathbb{Z}$  is connected, which by (weak) directedness implies the existence of a  $\preccurlyeq$ -maximum m. Earlier on we already discussed that we always have  $\operatorname{acd}(\mathbb{Z}) \le |\operatorname{Ran}(\Omega)|$  — we need to prove the oppositve inequality.

To see that  $|\mathsf{Ran}(\Omega)| \leq \mathsf{acd}(\mathbb{Z})$ , take an arbitrary  $z \in Z$ ; it is clear that  $h^{\uparrow}(z) \in [1, \mathsf{acd}(\mathbb{Z})]$ , so that we find  $\mathsf{acd}(\mathbb{Z}) - h^{\uparrow}(z) \in [0, \mathsf{acd}(\mathbb{Z}) - 1]$ . The second observation is then that, in the above definition of  $\Omega(z)$ , the elements of Z uniformly fall in one of the two mentioned cases. This means that we either have  $\mathsf{Ran}(\Omega) \subseteq [0, \mathsf{acd}(\mathbb{Z}) - 1]$  or  $\Omega[Z] \subseteq [1, \mathsf{acd}(\mathbb{Z})]$ . In both cases this means that  $|\mathsf{Ran}(\Omega)| \leq \mathsf{acd}(\mathbb{Z})$  as required. QED

**Example 6.34** The condition of weak directedness in Theorem 6.33 is necessary, as the following simple example witnesses:

This parity poset clearly has alternation depth 2, but it cannot be represented by any priority map with range of size  $\leq 2$ .

#### 6.3.2 Parity formulas on the subformula graph

The following theorem shows that for a clean formula, we can indeed obtain an equivalent parity formula which is based on its *subformula graph*, which we defined as the subformula dag, augmented with *back edges*.

**Theorem 6.35** There is an algorithm that constructs, for a clean formula  $\xi \in \mu ML(P)$ , an equivalent parity formula  $\mathbb{H}_{\xi}$  over P, based on the subformula graph of  $\xi$ , which satisfies  $|\mathbb{H}_{\xi}| = |\xi|^s$  and  $ind(\mathbb{H}_{\xi}) = ad(\xi)$ .

The basic idea underlying the proof of Theorem 6.35 is to view the evaluation games for clean formulas in  $\mu$ ML as instances of parity games. Given an arbitrary formula  $\xi \in \mu$ ML, we then need to see which modifications are needed to turn the subformula dag  $(Sf(\xi), \triangleright_0)$  into a parity formula  $\mathbb{H}_{\xi}$  such that, for any model  $\mathbb{S}$ , the evaluation games  $\mathcal{E}(\xi, \mathbb{S})$  and  $\mathcal{E}(\mathbb{H}_{\xi}, \mathbb{S})$ are more or less identical. Clearly, the fact that the *positions* of the evaluation game  $\mathcal{E}(\xi, \mathbb{S})$ are given as the pairs in the set  $Sf(\xi) \times S$ , means that we can take the set

$$V_{\xi} := Sf(\xi)$$

as the carrier of  $\mathbb{H}_{\xi}$  indeed.

Looking at the admissible moves in the two games, it turns out that we cannot just take the converse direct subformula relation  $\triangleright_0$  as the edge relation of  $\mathbb{H}_{\xi}$ : we need to add all *back edges* from the set

$$B_{\xi} := \{ (x, \delta_x) \mid x \in BV(\xi) \},\$$

where, as usual, we let  $\delta_x$  denote the unique formula such that, for some  $\eta \in \{\mu, \nu\}$  the formula  $\eta x \cdot \delta_x$  is a subformula of  $\xi$ . In fact, if we write  $D_{\xi}$  for the relation  $\triangleright_0$ , restricted to  $Sf(\xi)$ , then we can take

$$E_{\xi} := D_{\xi} \cup B_{\xi},$$

as the edge relation of  $\mathbb{H}_{\xi}$ . Furthermore, the labelling map  $L_{\xi}$  is naturally defined via the following case distinction:

$$L_{\xi}(\varphi) := \begin{cases} \varphi & \text{if } \varphi \in \{\top, \bot\} \cup \{p, \overline{p} \mid p \in FV(\xi)\} \\ \odot & \text{if } \varphi \text{ is of the form } \varphi_0 \odot \varphi_1 \text{ with } \odot \in \{\land, \lor\} \\ \heartsuit & \text{if } \varphi \text{ is of the form } \heartsuit \psi \text{ with } \heartsuit \in \{\diamondsuit, \Box\} \\ \varepsilon & \text{if } \varphi \text{ is of the form } \eta_x x. \delta_x \text{ with } \eta \in \{\mu, \nu\} \\ \varepsilon & \text{if } \varphi \in BV(\xi). \end{cases}$$

With this definition, it is easy to see that the *boards* of the two evaluation games  $\mathcal{E}(\xi, \mathbb{S})$  and  $\mathcal{E}(\mathbb{H}_{\xi}, \mathbb{S})$  are *isomorphic* (in fact, identical), for any labeled transition system  $\mathbb{S}$ . As the initial node  $v_{\xi}$  of  $\mathbb{H}_{\xi}$  we simply take

$$v_{\xi} := \xi.$$

In order to finish the definition of the parity formula  $\mathbb{H}_{\xi}$  it is then left to come up with a suitable priority map  $\Omega_{\xi}$  on  $V_{\xi}$ . For this we base ourselves on the discussion in the previous subsection, but rather than the unfolding order  $\leq_{\xi}$  we will consider the *depency order*  $\leq_{\xi}$ 

6-16

defined below. Intuitively,  $x \preccurlyeq_{\xi} y$  indicates not only that  $\delta_x$  is a subformula of  $\delta_y$ , but also that y is 'more significant' than x, in the sense that the meaning of  $x/\delta_x$  (in principle) depends on the meaning of  $y/\delta_y$ . The key situation where this happens is when y occurs freely in  $\delta_x$ .

**Definition 6.36** Given a clean formula  $\xi$ , we define a *dependency* or *subordination order*  $\preccurlyeq_{\xi}$  on the set  $BV(\xi)$ , saying that y ranks higher than x if  $x \preccurlyeq_{\xi} y$ . The relation  $\preccurlyeq_{\xi}$  is defined as the least partial order containing all pairs (x, y) such that  $y \preccurlyeq \delta_x \preccurlyeq \delta_y$ .

For an example where the two orders give a different alternation depth, we refer to the formula  $\xi_3$  in Example 2.52. The following Proposition shows that  $\preccurlyeq_{\xi}$  is a suitable alternative to  $\leqslant_{\xi}$ , in the sense that we will assign the same winner to any infinite match of the evaluation game, whether we base ourselves on  $\preccurlyeq_{\xi}$  or on  $\leqslant_{\xi}$ .

**Proposition 6.37** Let  $\xi$  be a clean  $\mu$ ML<sub>D</sub>-formula, and let  $\pi$  be an infinite match of the evaluation game  $\mathcal{E}(\xi, \mathbb{S})$ , for some model  $\mathbb{S}$ . Then

$$\max_{\preccurlyeq \xi} (Unf^{\infty}(\pi)) = \max_{\preccurlyeq \xi} (Unf^{\infty}(\pi)).$$

**Proof.** Abbreviate  $U := Unf^{\infty}(\pi)$ , and let  $y \in U$  be the maximum of U in terms of  $\leq_{\xi}$  — such a y exists by Proposition 2.24.

We claim that

$$x \preccurlyeq_{\xi} y, \text{ for all } x \in U.$$
 (63)

Suppose for contradiction that there is a variable  $x \in U$  with  $x \not\prec_{\xi} y$ . It follows from the assumption on y that  $\delta_x \leq \delta_y$ , and without loss of generality we may assume x to be such that  $\delta_x$  is a maximal subformula of  $\delta_y$  such that  $x \not\prec_{\xi} y$  (in the sense that  $z \prec_{\xi} y$  for all  $z \in U$  with  $\delta_x \triangleleft \delta_z$ ). In particular then we have  $y \notin FV(\delta_x)$ . But since y is unfolded infinitely often, there must be a variable  $z \in FV(\delta_x)$  which allows  $\pi$  to 'leave'  $\delta_x$  infinitely often; this means that  $z \in U$ ,  $\delta_x \leq \delta_z$  but  $\delta_z \not\leq \delta_x$ . From this it is immediate that  $x \prec_{\xi} z$ , while from  $z \in U$  we obtain  $\delta_z \leq \delta_y$ . It now follows from our maximality assumption on x that  $z \prec_{\xi} y$ . But then by transitivity of  $\prec_{\xi}$  we find that  $x \prec_{\xi} y$ . In other words, we have arrived at the desired contradiction.

This shows that (63) holds indeed, and from this the Proposition is immediate. QED

For our definition of  $\mathbb{H}_{\xi}$  we will take the priority map  $\Omega_{\xi}$  given by

$$\Omega_{\xi} := \Omega_{\preccurlyeq_{\xi}}$$

Note that  $\Omega_{\xi}$ , as a map on  $Sf(\xi)$ , is partial indeed: it is only defined for those subformulas of  $\xi$  that belong to its bound variables.

Summarizing, we define

$$\mathbb{H}_{\xi} := (V_{\xi}, E_{\xi}, L_{\xi}, \Omega_{\xi}, \xi).$$

**Proof of Theorem 6.35.** In the light of the above discussion, the equivalence of  $\xi$  and  $\mathbb{H}_{\xi}$  follows from the Propositions 6.28 and 6.37 (and the easily verified fact that  $\Omega_{\xi}$  satisfies the conditions 1 and 2 of Definition 6.27). It is immediate by the definitions that  $|\mathbb{H}_{\xi}| = |Sf(\xi)| = |\xi|^s$ . Finally, it follows from Theorem 6.33 that the index of  $\mathbb{H}_{\xi}$  is given by the alternating chain depth of  $\preccurlyeq_{\xi}$ . In order to get an *exact* match of the index of  $\mathbb{H}_{\xi}$  and the inductively defined alternation depth of  $\xi$  we need to work a bit harder: in Section 6.5 below we will prove Proposition 6.58 stating that  $\mathsf{ad}(\xi) = \mathsf{acd}(\preccurlyeq_{\xi})$ . QED

# 6.3.3 Parity formulas on the closure graph

The next theorem states that for a tidy formula, we can find an equivalent parity formula that is based on the formula's *closure graph*, and has an index which is bounded by the alternation depth of the formula. This result applies to *arbitrary* tidy formulas, that is: no renaming of the formula's bound variables or other kinds of preprocessing the formula are needed.

**Theorem 6.38** There is a construction transforming an arbitrary tidy formula  $\xi \in \mu$ ML into an equivalent balanced parity formula  $\mathbb{G}_{\xi}$  which is based on the closure graph of  $\xi$ , so that  $|\mathbb{G}| = |\xi|$ ; in addition we have  $ind(\mathbb{G}_{\xi}) \leq ad(\xi)$ .

When it comes to complexity issues, this is in fact the main result that bridges the gap between the world of formulas and that of automata and parity games.

**Theorem 6.39** Assume that the problem of determining the winning regions of a parity game  $\mathcal{G}$  can be solved in time f(n, d), where n and d are, respectively, the size and the index of  $\mathcal{G}$ . Then the model checking problem for parity formulas can be solved in time  $f(m \cdot n, d)$ , where m is the size of the labelled transition system, and n and d are the size and alternation depth of the formula, respectively.

In particular, as an immediate corollary of Theorem 6.38 and the quasi-polynomial time complexity result on the model checking problem for parity formulas (Theorem 6.12), we find that model checking for  $\mu$ -calculus formulas can be solved in quasi-polynomial time.

 COROLLARY: give concrete upper bound for complexity of model checking using Theorem 6.39 and Theorem 5.40.

The priority map  $\Omega_C$  that we will define on the closure graph of a tidy formula is in fact global in the sense that it can be defined uniformly for all (tidy) formulas, independently of any ambient formula. Similar to the case of the subformula game, the free subformula relation  $\leq_f$  used in Chapter 2 does not give an optimal result. We will rather base the map  $\Omega_C$  on a partial order of fixpoint formulas, the closure priority relation  $\leq_C$ , that we will introduce now.

**Definition 6.40** We let  $\equiv_C$  denote the equivalence relation generated by the trace relation  $\rightarrow_C$ , in the sense that:  $\varphi \equiv_C \psi$  if  $\varphi \twoheadrightarrow_C \psi$  and  $\psi \twoheadrightarrow_C \varphi$ . We will refer to the equivalence classes of  $\equiv_C$  as *(closure) clusters*, and denote the cluster of a formula  $\varphi$  as  $(\varphi)_C$ .

Furthermore, we define the *closure priority relation*  $\preccurlyeq_C$  on fixpoint formulas by putting  $\varphi \preccurlyeq_C \psi$  precisely if  $\psi \twoheadrightarrow^{\psi}_C \varphi$ , and we write  $\varphi \prec_C \psi$  if  $\varphi \preccurlyeq_C \psi$  and  $\psi \not\preccurlyeq_C \varphi$ .

In words:  $\varphi \preccurlyeq_C \psi$  if there is a trace from  $\psi$  to  $\varphi$  such that  $\psi$  is a (free) subformula of every formula on the trace. This definition is somewhat involved, but this seems to be unavoidable if we want an optimal complexity of model checking.

**Remark 6.41** The definition of the priority order  $\preccurlyeq_C$  may look overly complicated. In fact, simpler definitions would suffice if we are only after the equivalence of a tidy formula with an associated parity formula that is based on its closure graph, i.e., if we do not need an exact match of index and alternating-chain depth.

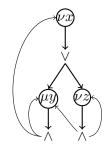

#### ▶ rewrite next paragraph

In particular, we could have introduced an alternative priority order  $\preccurlyeq'_C$  by putting  $\varphi \preccurlyeq'_C \psi$ if  $\varphi \equiv_C \psi$  and  $\psi \preccurlyeq_f \varphi$ . If we would base a priority map  $\Omega'_C$  on this priority order instead of on  $\preccurlyeq_C$ , then we could prove the equivalence of any tidy formula  $\xi$  with the associated parity formula  $\mathbb{G}'_{\xi} := (\mathbb{C}_{\xi}, \Omega'_C \upharpoonright_{Cl(\xi)}, \xi)$ . However, we would not be able to prove that the index of  $\mathbb{G}'_{\xi}$  is bounded by the alternation depth of  $\xi$ .

To see this, consider the following formula:

$$\alpha_x := \nu x. \big( (\mu y. x \land y) \lor \nu z. (z \land \mu y. x \land y) \big).$$

(For simplicity we use a formula without modalities to make the argument — nothing hinges on this.) We leave it for the reader to verify that  $\alpha_x$  has alternation depth two, and that its closure graph looks as follows:

Let  $\alpha_y$  and  $\alpha_z$  be the other two fixpoint formulas in the cluster of  $\alpha_x$ , that is, let  $\alpha_y := \mu y . \alpha_x \wedge y$  and  $\alpha_z := \nu z . z \wedge \alpha_y$ . (These formulas correspond to the nodes in the graph that are labelled  $\mu y$  and  $\nu z$ , respectively.) Now observe that we have  $\alpha_x \triangleleft_f \alpha_y \triangleleft_f \alpha_z$ , so that this cluster has an alternating  $\preccurlyeq'_C$ -chain of length *three*:  $\alpha_z \prec'_C \alpha_y \prec'_C \alpha_x$ . Note however, that any trace from  $\alpha_y$  to  $\alpha_z$  must pass through  $\alpha_x$ , the  $\preccurlyeq_C$ -maximal element of the cluster. In particular, we do *not* have  $\alpha_z \preccurlyeq_C \alpha_y$ , so that there is  $no \preccurlyeq_C$ -chain of length three in the cluster.

Here are some basic observations on the relation  $\preccurlyeq_C$  and its connection with the closure equivalence relation  $\equiv_C$ .

# **Proposition 6.42** 1) The relation $\preccurlyeq_C$ is a partial order.

- 2) The relation  $\preccurlyeq_C$  is included in the closure equivalence relation:  $\varphi \preccurlyeq_C \psi$  implies  $\varphi \equiv_C \psi$ .
- 3) The relation  $\preccurlyeq_C$  is included in the converse free subformula relation:  $\varphi \preccurlyeq_C \psi$  implies  $\psi \preccurlyeq_f \varphi$ .
- 4) Every cell of  $\equiv_C$  contains a unique fixpoint formula  $\xi = \eta x.\chi$  such that  $\xi \notin Cl(\chi)$ . This formula is the  $\preccurlyeq_C$ -maximum element of its cluster.

**Proof.** For item 1) we need to show that  $\preccurlyeq_C$  is reflexive, transitive and antisymmetric. Reflexivity is obvious, and antisymmetry follows from 3). For transitivity assume that  $\varphi \preccurlyeq_C \psi$ and  $\psi \preccurlyeq_C \chi$  hold. By definition this means that  $\psi \twoheadrightarrow^{\psi}_C \varphi$  and  $\chi \twoheadrightarrow^{\chi}_C \psi$ . The latter entails that  $\chi \preccurlyeq_f \psi$  and the former means that there is some  $\rightarrow_C$ -trace from  $\psi$  to  $\varphi$  such that  $\psi$ is a free subformula of every formula along this trace. Because  $\chi \preccurlyeq_f \psi$  and  $\preccurlyeq_f$  is transitive it then also holds that  $\chi$  is a free subformula of every formula on the trace from  $\psi$  to  $\varphi$ . Composing this trace with the one from  $\chi$  to  $\psi$  we obtain a trace from  $\chi$  to  $\varphi$  such that  $\chi$  is a free subformula of all formulas along this trace. Hence  $\chi \twoheadrightarrow_C^{\chi} \varphi$  and so  $\varphi \preccurlyeq_C \chi$ .

For item 2) we assume that  $\varphi \preccurlyeq_C \psi$  and need to show that  $\varphi \twoheadrightarrow_C \psi$  and  $\psi \twoheadrightarrow_C \varphi$ . The assumption  $\varphi \preccurlyeq_C \psi$  means that  $\psi \twoheadrightarrow^{\psi}_C \varphi$  which clearly entails  $\psi \twoheadrightarrow_C \varphi$ . But, as already observed above,  $\psi \twoheadrightarrow^{\psi}_C \varphi$  also entails that  $\psi \preccurlyeq_f \varphi$ , from which  $\varphi \twoheadrightarrow_C \psi$  follows by Proposition 2.58.

Item 3) is immediate by the definition of  $\preccurlyeq_C$ .

Finally, consider item 4). We first argue that

every cluster of 
$$\rightarrow_C$$
 contains a fixpoint formula  $\xi = \eta x \cdot \chi \notin Cl(\chi)$ . (64)

To this aim we claim that if  $\xi = \eta x \cdot \chi$  and  $\xi \in Cl(\chi)$  then there is some fixpoint formula  $\psi \in (\xi)_C$  with  $\xi \prec_C \psi$ . To see this, consider some  $\xi = \eta x \cdot \chi$  with  $\xi \in Cl(\chi)$ . Then we have a trace  $\chi \twoheadrightarrow_C \xi$  to which we can apply Proposition 2.39 to obtain a fixpoint formula  $\psi$  with  $\chi \twoheadrightarrow_C^{\psi} \psi$  and  $\psi \twoheadrightarrow_C^{\psi} \xi$ . From the latter we have that  $\xi \preccurlyeq_C \psi$  and from the former we get  $\psi \preccurlyeq_f \chi$  which entails  $\psi \neq \xi$  because  $\xi = \eta x \cdot \chi$ .

But if a cluster would only contain fixpoint formulas  $\xi = \eta x \cdot \chi$  with  $\xi$  in  $Cl(\chi)$  then this would allow us to construct an infinite  $\prec_C$ -chain in the cluster, which is impossible as all clusters are finite. This proves (64).

Uniqueness of the fixpoint formula  $\xi$  in (64) is immediate by the following claim:

if 
$$\xi = \eta x \cdot \chi$$
 and  $\xi \notin Cl(\chi)$  then  $\xi \leq \rho$ , for all  $\rho \in (\xi)_C$ . (65)

For the proof of (65), take an arbitrary  $\rho \in Cl(\xi)$ . It follows by Proposition 2.44 5) that either  $\rho = \xi$ , in which case we are done, or  $\rho = \gamma[\xi/x]$  for some  $\gamma \in Cl(\chi)$ . Now  $x \in FV(\gamma)$ because otherwise  $\chi \twoheadrightarrow_C \gamma = \gamma[\xi/x] = \rho \twoheadrightarrow_C \xi$  contradicting  $\xi \notin Cl(\chi)$ . But if  $\rho = \gamma[\xi/x]$ and  $x \in FV(\gamma)$  then by definition we have  $\xi \leq_f \rho$ . This finishes the proof of (65).

For the  $\preccurlyeq_C$ -maximality of  $\xi$  consider an arbitrary fixpoint formula  $\psi \in (\xi)_C$ . Then we have  $\xi \twoheadrightarrow_C \psi$ , and since every formula  $\rho$  on this trace  $\xi \twoheadrightarrow_C \psi$  is in  $(\xi)_C$  it follows from (65) that  $\xi \preccurlyeq_f \rho$  and thus  $\xi \twoheadrightarrow_C^{\xi} \psi$ . By definition this means  $\psi \preccurlyeq_C \xi$ . QED

Since  $\preccurlyeq_C$  is a partial order, we may use Definition 6.27 to base a priority map on it. We are now ready for the definition of the parity formula  $\mathbb{G}_{\xi}$  corresponding to a tidy formula  $\xi$ .

**Definition 6.43** Fix some tidy formula  $\xi$ . We define  $\mathbb{C}_{\xi}$  to be the closure graph  $(Cl(\xi), \rightarrow_C)$  of  $\xi$ , expanded with the natural labelling  $L_C$  given by

$$L_C(\varphi) = \begin{cases} \varphi & \text{if } \varphi \in \mathsf{At}(\mathsf{P}) \\ \heartsuit & \text{if } \varphi = \heartsuit\psi, & \text{with } \heartsuit \in \{\diamondsuit, \Box\} \\ \odot & \text{if } \varphi = \psi_0 \odot \psi_1, & \text{with } \odot \in \{\land, \lor\} \\ \varepsilon & \text{if } \varphi = \eta x.\psi, & \text{with } \eta \in \{\mu, \nu\} \end{cases}$$

Finally, we let  $\mathbb{G}_{\xi}$  be the parity formula

$$\mathbb{G}_{\xi} := (\mathbb{C}_{\xi}, \Omega_C \upharpoonright_{Cl(\xi)}, \xi),$$

where  $\Omega_C$  is the priority map that is induced by the partial order  $\preccurlyeq_C$ ; in particular,  $\Omega_C$  is a partial map on tidy formulas that is only defined for fixpoint formulas.

**Proof of Theorem 6.38.** It is obvious that  $\mathbb{G}_{\xi}$  is based on the closure graph of  $\xi$ , and it follows from the discussion in subsection 6.3.1 that the index of  $\mathbb{G}_{\xi}$  is equal to the alternating chain depth of the relation  $\preccurlyeq_C$ . It then follows from Proposition 6.61 that  $ind(\mathbb{G}_{\xi}) \leq ad(\xi)$ . The remaining statement of the Theorem, that is, the equivalence of  $\mathbb{G}_{\xi}$  and  $\xi$ , will be proved below, cf. Proposition 6.47. QED

The remainder of this section is devoted to proving the equivalence of a tidy formula  $\xi$  to its representing parity formula  $\mathbb{G}_{\xi}$ . For this purpose we need some auxiliary technical results. The following proposition states that the global priority map indeed captures the right winner of infinite matches of the evaluation game. Recall that the winner of an infinite match  $\pi$  of the closure evaluation game is given by the parity of the most significant formula  $\mathtt{msf}(\pi_L)$  on the trace part of  $\pi$  (that is, the left projection  $\pi_L$  of  $\pi$ .

**Proposition 6.44** Let  $\tau = (\xi_n)_{n \in \omega}$  be an infinite trace of tidy formulas, and that  $\xi = \eta x \chi$  is the most significant formula of  $\tau$ . Then

- 1)  $\xi$  is the unique formula which occurs infinitely often on  $\tau$  and satisfies  $\xi_n \preccurlyeq_C \xi$  for cofinitely many n.
- 2)  $\max\left(\{\Omega(\varphi) \mid \varphi \text{ occurs infinitely often on } \tau\}\right)$  is even iff  $\eta = \nu$ .

**Proof.** Part 1) is more or less immediate by the Propositions 2.39 and 2.58. From this it follows by Proposition 6.33 that  $\Omega_C(\varphi) \leq \Omega_C(\xi)$  for all  $\varphi$  that occur infinitely often on  $\tau$ , and that  $\Omega_C(\xi)$  has the right parity. This proves Part 2). QED

The following proposition describes the relation between the substitution operation and the free subformula relation.

**Proposition 6.45** Let  $\varphi$ ,  $\psi$  and  $\xi$  be formulas in  $\mu$ ML such that  $x \in FV(\varphi)$ , and  $\xi$  is free for x in both  $\varphi$  and  $\psi$ . Then

1)  $\varphi \leq_f \psi$  implies  $\varphi[\xi/x] \leq_f \psi[\xi/x];$ 

2)  $\varphi[\xi/x] \leq_f \psi[\xi/x]$  implies  $\varphi \leq_f \psi$ , provided that  $\xi \not\leq_f \varphi, \psi$ .

**Proof.** For part 1), assume that  $\varphi \leq_f \psi$ , then  $\psi = \psi'[\varphi/y]$  for some formula  $\psi'$  such that  $y \in FV(\psi')$  and  $\varphi$  is free for y in  $\psi'$ . Without loss of generality we may assume that y does not occur in  $\psi$ . Then by Proposition 2.55 we obtain that  $\varphi[\xi/x]$  is free for y in  $\psi'[\xi/x]$ , and that  $\psi'[\xi/x][\varphi[\xi/x]/y] = \psi[\xi/x]$ . This means that  $\varphi[\xi/x] \leq_f \psi[\xi/x]$  indeed.

For part 2), clearly it suffices to show that

if 
$$\psi[\xi/x] = \rho[\varphi[\xi/x]/y]$$
 with  $y \in FV(\rho)$  then  $\psi = \rho'[\varphi/y]$ , for some  $\rho'$  with  $y \in FV(\rho')$ .  
(66)

We will prove (66) by induction on the maximal depth  $d_y(\rho)$  of y in  $\rho$  which we define as follows:

$$\begin{aligned} d_y(\rho) &:= \begin{cases} 0 & \text{if } \rho = y \\ -\infty & \text{if } \rho \text{ is atomic but } \rho \neq y \end{cases} \\ d_y(\rho_0 \star \rho_1) &:= 1 + \max(d_y(\rho_0), d_y(\rho_1)) & (\star \in \{\lor, \land\}) \\ d_y(\heartsuit \rho) &:= 1 + d_y(\heartsuit \rho) & (\heartsuit \in \{\diamondsuit, \square\}) \\ d_y(\eta z \rho) &:= \begin{cases} 1 + d_y(\heartsuit \rho) & \text{if } y \neq z \\ -\infty & \text{if } y = z \end{cases} \end{aligned}$$

As the basis of our induction we take the cases where  $d_y(\rho) \leq 0$ . First assume  $d_y(\rho) = -\infty$ , which means that  $y \notin FV(\rho)$ , so that  $\rho[\varphi[\xi/x]/y] = \rho$ . In this case (66) holds vacuously.

In the other base case we assume  $d_y(\rho) = 0$ , which means that  $\rho = y$ , so that  $\rho[\varphi[\xi/x]/y] = \varphi[\xi/x]$ . But then the equation of (66) reads  $\psi[\xi/x] = \varphi[\xi/x]$ , so that we find  $\psi = \varphi$  by Proposition 2.59; that is, we may take  $\rho' := y$ .

In the induction step of the proof we have  $d_y(\rho) > 0$ , from which we readily infer that  $\rho$  is non-atomic and that  $y \in FV(\rho)$ . From this it is immediate that  $\xi$  is a *proper* subformula of  $\rho[\varphi[\xi/x]/y]$ . Now make a case distinction as to the nature of  $\rho$ , and confine attention to the following two cases.

First assume that  $\rho = \rho_0 \wedge \rho_1$ , so that the equation in (66) reads  $\psi[\xi/x] = \rho_0[\varphi[\xi/x]/y] \wedge \rho_1[\varphi[\xi/x]/y]$ . It follows that  $\psi$  must be of the form  $\psi_0 \wedge \psi_1$  with  $\psi_i[\xi/x] = \rho_i[\varphi[\xi/x]/y]$  for i = 0, 1 — for otherwise we would have  $\psi = x$ , which would imply  $\psi[\xi/x] = \xi$  and thus contradict our observation that  $\xi \triangleleft \rho[\varphi[\xi/x]/y]$ . But then inductively there are formulas  $\rho'_i$  such that  $\psi_i = \rho'_i[\varphi/x]$ , with  $y \in FV(\rho_i)$  iff  $y \in FV(\rho'_i)$ , for i = 0, 1. It is then straightforward to verify that  $\rho' := \rho'_0 \wedge \rho'_1$  meets the requirement.

Now assume that  $\rho = \eta z \rho_0$ . Then it must be the case that  $\psi = \eta z \psi_0$ , with  $\psi_0[\xi/x] = \rho_0[\varphi[\xi/x]/y]$ . (The only other option would be that  $\psi = x$ , which would mean that the equation in (66) would read  $\xi = \rho[\varphi[\xi/x]/y]$ , again contradicting the fact that  $\xi$  is a proper subformula of  $\rho[\varphi[\xi/x]/y]$ .) By the inductive hypothesis there is a formula  $\rho'_0$  with  $y \in FV(\rho_0)$  such that  $\psi_0 \equiv \rho'_0[\varphi/y]$ . Now define  $\rho' := \eta z \rho'_0$ , then we find  $y \in FV(\rho')$ , and  $\rho'[\varphi/y] = \eta z \phi'_0[\varphi/y] = \eta z \psi_0 = \psi$ . QED

▶ Exercise: show that conditions  $\xi \not \leq_f \varphi, \psi$  are both needed.

The next proposition is the key technical ingredient in proving the equivalence of  $\xi$  and  $\mathbb{G}_{\xi}$ , in the inductive case where  $\xi$  is of the form  $\eta x.\chi$ . Roughly, it states that the substitution  $\xi/x$  is 'almost an isomorphism' between  $\mathbb{G}_{\chi}$  and  $\mathbb{G}_{\xi}$ ; note, however, that actually, rather than  $\chi$  we consider its variant  $\chi' := \chi[x'/x]$  — this guarantees tidyness. Recall that the alternation height  $h^{\downarrow}(\xi)$  of a formula  $\xi$  was introduced in Definition 6.32

**Proposition 6.46** Let  $\xi = \eta x \cdot \chi$  be a tidy fixpoint formula such that  $x \in FV(\chi)$  and  $\xi \notin Cl(\chi)$ . Furthermore, let  $\chi' := \chi[x'/x]$  for some fresh variable x'. Then  $\chi'$  is tidy and the following hold.

1) the substitution  $\xi/x'$  is a bijection between  $Cl(\chi')$  and  $Cl(\xi)$ . Let  $\varphi, \psi \in Cl(\chi')$ . Then we have

- 2) if  $\varphi \neq x'$ , then  $\varphi \rightarrow_C \psi$  iff  $\varphi[\xi/x'] \rightarrow_C \psi[\xi/x']$ ;
- 3) if  $\varphi \neq x'$ , then  $L_C(\varphi) = L_C(\varphi[\xi/x'])$ ;
- 4) if  $x' \in FV(\varphi)$  then  $\varphi \leq_f \psi$  iff  $\varphi[\xi/x'] \leq_f \psi[\xi/x']$ ;
- 5) if  $\varphi$  and  $\psi$  are fixpoint formulas then  $\psi \preccurlyeq_C \varphi$  iff  $\psi[\xi/x'] \preccurlyeq_C \varphi[\xi/x'];$
- 6) if  $(\varphi_n)_{n \in \omega}$  is an infinite trace through  $Cl(\chi')$ , then  $(\varphi_n)_{n \in \omega}$  has the same winner as  $(\varphi_n[\xi/x'])_{n \in \omega}$ .

**Proof.** Let  $\xi = \eta x \cdot \chi$  be a tidy fixpoint formula such that  $x \in FV(\chi)$  and  $\xi \notin Cl(\chi)$ , and let  $\chi' := \chi[x'/x]$  for some fresh variable x'. We leave it for the reader to verify that  $\chi'$  is tidy, and first make the following technical observation:

if 
$$\varphi \in Cl(\chi')$$
 then  $\xi \notin Cl(\varphi)$  and  $\xi \not \approx_f \varphi$ . (67)

Leaving the proof of (67) to the reader, we turn to the respective items of the Proposition.

*Item 1):* Injectivity can be proved using Proposition 2.59, surjectivity using Proposition 2.44.

*Item 2):* This follows immediately from the 'back-and-forth lemma' (Proposition 2.56) and item 1).

Item 3): The claim that  $L_C(\varphi) = L_C(\varphi[\xi/x'])$  is rather trivial.

Item 4): This is Proposition 6.45. The assumptions  $\xi \not \leq_f \psi$  and  $\xi \not \leq_f \varphi$  follow from (67).

Item 5): For the left-to-right direction assume that  $\psi \preccurlyeq_C \varphi$ . By definition there is some trace  $\varphi = \rho_0 \rightarrow_C \rho_1 \rightarrow_C \ldots \rightarrow_C \rho_n = \psi$  such that  $\varphi \preccurlyeq_f \rho_i$  for all  $i \in [0, n]$ . It is clear that none of the  $\rho_i$  is equal to x because x has no outgoing  $\rightarrow_C$ -edges and  $\psi \neq x'$ . Thus we can use item 2) to obtain a trace  $\varphi[\xi/x'] = \rho_0[\xi/x'] \rightarrow_C \rho_1[\xi/x'] \rightarrow_C \ldots \rightarrow_C \rho_n[\xi/x'] = \psi[\xi/x']$ . By Proposition 6.45 it follows from  $\varphi \preccurlyeq_f \rho_i$  that  $\varphi[\xi/x'] \preccurlyeq_f \rho_i[\xi/x']$ , for all  $i \in [0, n]$ . That is, we have shown that  $\varphi[\xi/x'] \rightarrow_C \varphi_C[\xi/x']$ .

Before we turn to the opposite direction we show that, for all  $\rho, \sigma \in Cl(\chi')$ , we have

if 
$$\rho[\xi/x'] \twoheadrightarrow_C \sigma[\xi/x']$$
 and  $x' \in FV(\sigma)$  then  $x' \in FV(\rho)$ . (68)

This claim holds because, since  $\xi$  is free for x' in  $\sigma$ , by definition of  $\leq_f$  it follows from  $x' \in FV(\sigma)$  that  $\xi \leq_f \sigma[\xi/x']$ , and thus we find  $\sigma[\xi/x'] \twoheadrightarrow_C \xi$  by Proposition 2.58. If it were the case that  $x' \notin FV(\rho)$  then we would have that  $\rho = \rho[\xi/x'] \twoheadrightarrow_C \sigma[\xi/x'] \twoheadrightarrow_C \xi$ , contradicting (67).

Turning to the right-to-left direction of item 5), assume that  $\psi[\xi/x'] \preccurlyeq_C \varphi[\xi/x']$ . This means that there is a trace  $\varphi[\xi/x'] = \rho'_0 \rightarrow_C \ldots \rightarrow_C \rho'_m = \psi[\xi/x']$  with  $\varphi[\xi/x'] \preccurlyeq_f \rho'_i$ for all  $i \in [0, m]$ . By Proposition 6.42 we have  $\psi[\xi/x'] \equiv_C \varphi[\xi/x']$ . It follows from (68) and  $\psi[\xi/x'] \equiv_C \varphi[\xi/x']$  that x' is either free in both  $\varphi$  and  $\psi$ , or free in neither of the two formulas. In the second case we obtain  $\varphi = \varphi[\xi/x']$  and  $\psi = \psi[\xi/x']$ , so that the statement of this item holds trivially.

We now focus on the case where  $x' \in FV(\varphi) \cap FV(\psi)$ . Our first claim is that  $\rho'_i \neq \xi$ for all  $i \in [0, m]$ . This follows from the fact that  $\varphi[\xi/x'] \leq_f \rho'_i$ , which holds by assumption, and the observation that  $\xi$  is a proper free subformula of  $\varphi[\xi/x']$ , which holds since  $\varphi$  is a fixpoint formula and hence, distinct from x'. But if  $\rho'_i \neq \xi$  for all  $i \in [0, m]$ , we may use the items 1) and 2) to obtain a trace  $\varphi = \rho_0 \to_C \ldots \to_C \rho_m = \psi$  such that  $\rho_i[\xi/x'] = \rho'_i$  for all  $i \in [0, m]$ . Furthermore, by Proposition 2.42 it follows from  $x' \in FV(\psi)$  that  $x' \in FV(\rho_i)$ , and so we may use item 4) to obtain  $\varphi \leq_f \rho_i$ , for all  $i \in [0, m]$ . This suffices to show that  $\psi \leq_C \varphi$ .

Item 6): This observation is immediate by item 5) and Proposition 6.44. QED

**Proposition 6.47** Let  $\xi$  be a tidy  $\mu$ -calculus formula. Then  $\xi \equiv \mathbb{G}_{\xi}$ .

**Proof.** It will be convenient to consider the global formula graph  $\mathbb{G} := (\mu \mathbb{ML}^t, \rightarrow_C, L_C, \Omega_C)$ , where  $\mu \mathbb{ML}^t$  is the set of all tidy formulas using a fixed infinite set of variables, and  $L_C$  is the

obviously defined global labelling function. We may assign a semantics to this global graph using an equally obvious definition of an acceptance game, where the only non-standard aspect is that the carrier set of this 'formula' is infinite. For each tidy formula  $\varphi$  we may then consider the structure  $\mathbb{G}\langle\varphi\rangle := (\mu \mathsf{ML}^t, \to_C, L_C, \Omega_C, \varphi)$  as an initialised (generalised) parity formula. Note that all structures of this form have the same (infinite) set of vertices, but that the only vertices that are accessible in  $\mathbb{G}\langle\varphi\rangle$  are the formulas in the (finite) set  $Cl(\varphi)$ . It is then easy to see that  $\mathbb{G}\langle\varphi\rangle \equiv \mathbb{G}_{\xi}\langle\varphi\rangle$ , for any pair of tidy formulas  $\varphi$ ,  $\xi$  such that  $\varphi \in Cl(\xi)$ .

In order to prove the Proposition, it therefore suffices to show that every tidy formula  $\xi$  satisfies the following:

$$\mathbb{G}\langle\varphi\rangle \equiv \varphi, \text{ for all } \varphi \in Cl(\xi).$$
(69)

We will prove (69) by induction on the length of  $\xi$ . In the base step of this induction we have  $|\xi|^{\ell} = 1$ , which means that  $\xi$  is an atomic formula. In this case it is easy to see that (69) holds.

In the induction step of the proof we assume that  $|\xi|^{\ell} > 1$ , and we make a case distinction. The cases where  $\xi$  is of the form  $\xi = \xi_0 \odot \xi_1$  with  $\odot \in \{\land,\lor\}$  or  $\xi = \heartsuit \xi_0$  with  $\heartsuit \in \{\diamondsuit,\Box\}$ , are easy and left as exercises for the reader.

In the case where  $\xi$  is of the form  $\xi = \eta x \cdot \chi$  with  $\eta \in \{\mu, \nu\}$  we make a further case distinction. If  $\xi$  belongs to the closure set of  $\chi$ , then we have  $Cl(\xi) \subseteq Cl(\chi)$ , so that (69) immediately follows from the induction hypothesis, applied to the formula  $\chi$ .

This leaves the case where  $\xi$  is of the form  $\eta x.\chi$ , while  $\xi \notin Cl(\chi)$ . Let x' be some fresh variable, then obviously we may apply the induction hypothesis to the (tidy) formula  $\chi' := \chi[x'/x]$ . The statement that  $\xi \equiv \mathbb{G}\langle \xi \rangle$  now follows by a routine argument, based on the observations in Proposition 6.46. QED •

# 6.4 From parity formulas to ordinary formulas

In section 6.3 we saw constructions that, for a given ordinary formula, produce equivalent parity formulas based on, respectively, the subformula graph and the closure graph of the original formula. We will now move in the opposite direction: we will give a construction that turns an arbitrary parity formula  $\mathbb{G}$  into an equivalent ordinary formula  $\xi_{\mathbb{G}} \in \mu$ ML. Basically this construction takes a parity formulas as a system of equations, and it solves these equations by a Gaussian elimination of variables.

Interestingly, we encounter a significant difference between the two size measures introduced in Definition 2.48: whereas the closure-size of the resulting formula  $\xi_{\mathbb{G}}$  is *linear* in the size of  $\mathbb{G}$ , its number of subformulas is only guaranteed to be exponential. And in fact, Proposition 6.55 shows that there is a family of parity formulas for which the translation actually reaches this exponential subformula-size.

The main result in this section is the following.

**Theorem 6.48** There is an effective procedure which transforms a parity formula  $\mathbb{G} = (V, E, L, \Omega, v_I)$  over some set  $\mathsf{P}$  of proposition letters, into a  $\mu\mathsf{ML}$ -formula  $\xi_{\mathbb{G}}$  such that  $\xi_{\mathbb{G}} \equiv \mathbb{G}$ ,  $|\xi_{\mathbb{G}}| \leq 2 \cdot |\mathbb{G}|$  and  $\mathsf{ad}(\xi_{\mathbb{G}}) \leq ind(\mathbb{G})$ .

In order to prove Theorem 6.48 we will supply a map

$$\operatorname{tr}_{\mathbb{G}}: V \to \mu \operatorname{ML}(\mathsf{P})$$

for every balanced parity formula  $\mathbb{G} = (V, E, L, \Omega, v_I)$  over some set P of proposition letters. For an arbitrary parity formula  $\mathbb{G}$  we then obtain the formula  $\xi_{\mathbb{G}}$  by taking some balanced version  $\mathbb{G}'$  of  $\mathbb{G}$  and apply the translation  $\operatorname{tr}_{\mathbb{G}'}$  to the initial vertex of  $\mathbb{G}'$ .

The definition of the map  $tr_{\mathbb{G}}$ , just like most definitions and proofs in this section will proceed by an induction on a certain complexity measure of parity formulas that we shall refer to as *weight*.

**Definition 6.49** We define the *weight* of a parity formula  $\mathbb{G} = (V, E, L, \Omega, v_I)$  as the pair  $(|\mathsf{Dom}(\Omega)|, |\mathbb{G}|)$  consisting of, respectively, the number of states and the size of  $\mathbb{G}$ . Pairs of this form will be ordered lexicographically.

**Definition 6.50** Consider a balanced parity formula  $\mathbb{G} = (V, E, L, \Omega, v_I)$ , and let T be the top cluster of  $\mathbb{G}$ , that is, the cluster of the initial state  $v_I$ . We make the following case distinction.

Case 1: T is transient. In this case we must have  $T = \{v_I\}$ , with  $v_I \notin \mathsf{Ran}(E)$ , and for every  $u \neq v_I$  we may consider the parity formula  $G^-\langle u \rangle$  obtained by removing  $v_I$  from  $\mathbb{G}$ and making u the initial node. Each parity formula  $\mathbb{G}^-\langle u \rangle$  has the same number of states as  $\mathbb{G}$ , but less vertices, so that inductively we may assume that we have defined some formula  $\operatorname{tr}_{\mathbb{G}^-}(u)$  for each  $u \neq v_I$ . (Here we write  $\operatorname{tr}_{\mathbb{G}^-}$  instead of  $\operatorname{tr}_{\mathbb{G}^-\langle u \rangle}$ ; this is justified since the translation we define does not depend on the initial node.)

We define

$$\operatorname{tr}_{\mathbb{G}}(u) := \operatorname{tr}_{\mathbb{G}^{-}}(u)$$

Lectures on the modal  $\mu$ -calculus

for  $u \neq v_I$ , while for  $v_I$  we set<sup>5</sup>

$$\operatorname{tr}_{\mathbb{G}}(v_{I}) := \begin{cases} L(v_{I}) & \text{if } L(v_{I}) \in \operatorname{At}(\mathsf{P}) \\ \heartsuit \operatorname{tr}_{\mathbb{G}^{-}}(u) & \text{if } L(v) = \heartsuit \in \{\diamondsuit, \Box\} \text{ and } E(v) = \{u\} \\ \bigcirc \{\operatorname{tr}_{\mathbb{G}^{-}}(u) \mid u \in E(v)\} & \text{if } L(v) = \odot \in \{\land, \lor\} \end{cases}$$

Case 2: T is proper. In this case we have  $T \cap \mathsf{Dom}(\Omega) \neq \emptyset$ . Take an arbitrary state  $z \in T$  such that  $\Omega(z)$  equals the maximal priority reached on T. Since  $\mathbb{G}$  is balanced, z is silent (that is,  $L(z) = \varepsilon$ ); let z' be its unique successor.

Consider the parity formula  $\mathbb{G}^- = (V, E^-, L^-, \Omega^-, v_I)$ , which is characterised by the definition of  $E^-$ :

$$E^- := E \setminus \{(z, z')\},\$$

that is, we obtain  $E^-$  from E by cutting the edge from z to z'. Furthermore, we define

$$L^{-}(v) := \begin{cases} L(v) & \text{if } v \neq z \\ z & \text{if } v = z, \end{cases}$$

that is,  $\mathbb{G}^-$  sees z as a proposition letter. Finally, we set  $\Omega^- := \Omega \upharpoonright_{V \setminus \{z\}}$ , so that  $\mathbb{G}^-$  has one state less than  $\mathbb{G}$ .

Inductively, then, we may assume that for all  $v \in V$ , some formula  $tr_{\mathbb{G}^-}(v)$  has been defined, and observe that  $tr_{\mathbb{G}^-}(z) = z$ . We now define

$$\mathtt{tr}_{\mathbb{G}}(v) := \mathtt{tr}_{\mathbb{G}^-}(v)[\eta_z z.\mathtt{tr}_{\mathbb{G}^-}(z')/z]$$

where  $\eta_z := \mu$  if  $\Omega(z)$  is odd, and  $\eta_z := \nu$  if  $\Omega(z)$  is even.

▶ Example to be supplied!

**Remark 6.51** Before we turn to more interesting properties we note that the translation  $tr_{\mathbb{G}}$  is *well-defined*.

▶ some detail to be supplied

Note in particular that, although the definition of the translation map  $tr_{\mathbb{G}}$  involves many substitution operations, it does *not* involve any renaming of variables.

**Definition 6.52** Let  $\mathbb{G}$  be an arbitrary parity formula. If  $\mathbb{G}$  is balanced, we define

$$\xi_{\mathbb{G}} := \operatorname{tr}_{\mathbb{G}}(v_I),$$

where  $v_I$  is the initial vertex of  $\mathbb{G}$ . If  $\mathbb{G}$  is not balanced, we put  $\xi_{\mathbb{G}} := \xi_{\mathbb{G}^b}$ , where  $\mathbb{G}^b$  is some effectively obtainable balanced formula which is equivalent to  $\mathbb{G}$  and satisfies  $|\mathbb{G}^b| \leq 2 \cdot |\mathbb{G}|$  and  $ind(\mathbb{G}^b) = ind(\mathbb{G})$ .

 $\triangleleft$ 

<sup>&</sup>lt;sup>5</sup>Note that the formulation of the boolean clause of our definition (i.e., the case where  $L(v) = \odot \in \{\land,\lor\}$ ) is a bit sloppy, since our language only has binary conjunctions and disjunctions, no conjunctions or disjunctions over finite sets. A more precise definition can be given as follows; assume that  $\odot = \land$ , the case where  $\odot = \lor$ is treated analogously. Assume that we have some arbitrary but fixed ordering of the vertices in  $\mathbb{G}$ . We put  $\operatorname{tr}_{\mathbb{G}}(v) = \top$  if  $E(v) = \emptyset$ ,  $\operatorname{tr}_{\mathbb{G}}(v) = \operatorname{tr}_{\mathbb{G}}(u)$  if  $E(v) = \{u\}$ , and  $\operatorname{tr}_{\mathbb{G}}(v) = \operatorname{tr}_{\mathbb{G}}(u_0) \land (\ldots \land (\operatorname{tr}_{\mathbb{G}}(u_{k-1}) \land \operatorname{tr}_{\mathbb{G}}(u_k))$ if  $E(v) = \{u_0, \ldots, u_k\}$  where each  $u_i$  comes before  $u_{i+1}$  in the mentioned ordering.

The crucial technical lemma in the proof of Theorem 6.48 is the following proposition.

**Proposition 6.53** Let  $\mathbb{G}$  be a balanced parity formula. Then the map  $tr_{\mathbb{G}}$  is a surjective parity formula morphism:

 $\operatorname{tr}_{\mathbb{G}}: \mathbb{G} \twoheadrightarrow \mathbb{G}_{\xi_{\mathbb{G}}}.$ 

**Proof.** We will prove the proposition via a series of claims. Let  $\mathbb{G} = (V, E, L, \Omega, v_I)$  be a balanced parity formula. First we show that  $\mathtt{tr}_{\mathbb{G}}$  is a surjection from V to  $Cl(\xi_{\mathbb{G}})$ .

CLAIM 1  $\operatorname{tr}_{\mathbb{G}}[V] = Cl(\xi_{\mathbb{G}}).$ 

Proof of Claim By induction on the weight of  $\mathbb{G}$  we will prove the following two statements:

1)  $\operatorname{tr}_{\mathbb{G}}(v) \in Cl(\xi_{\mathbb{G}})$ , for all  $v \in V$ ;

2)  $Cl(\xi_{\mathbb{G}}) \subseteq \operatorname{tr}_{\mathbb{G}}[V].$ 

As in Definition 6.50, we let T be the top cluster of  $\mathbb{G}$ , and make a case distinction. Leaving the case where T is transient as an exercise, we focus on the case where T is proper, and we let z and  $\mathbb{G}^-$  be as in Definition 6.50. We abbreviate  $\tau := [\operatorname{tr}_{\mathbb{G}}(z)/z]$ , and we define the *closure of*  $\mathbb{G}$  as follows:

$$Cl(\mathbb{G}) := \bigcup \big\{ Cl(\operatorname{tr}_{\mathbb{G}}(v)) \mid v \in V \big\}.$$

For part 1) we first observe that  $\xi_{\mathbb{G}} = \operatorname{tr}_{\mathbb{G}}(v_I) = \operatorname{tr}_{\mathbb{G}^-}(v_I)[\tau] = \xi_{\mathbb{G}^-}[\tau]$ . From this it follows by Proposition 2.44 that  $Cl(\xi_{\mathbb{G}}) \supseteq \{\varphi[\tau] \mid \varphi \in Cl(\xi_{\mathbb{G}^-})\}$ . Now take an arbitrary vertex  $v \in V$ . Then by the inductive hypothesis we have  $\operatorname{tr}_{\mathbb{G}^-}(v) \in Cl(\xi_{\mathbb{G}^-})$ , so that  $\operatorname{tr}_{\mathbb{G}^-}(v)[\tau] \in \{\varphi[\tau] \mid \varphi \in Cl(\xi_{\mathbb{G}^-})\} \subseteq Cl(\xi_{\mathbb{G}})$  as required.

For part 2) our key observation is that

$$Cl(\mathbb{G}) \subseteq \{\varphi[\tau] \mid \varphi \in Cl(\mathbb{G}^{-})\},$$
(70)

where  $\tau$  is the substitution  $\tau = [tr_{\mathbb{G}}(z)/z]$ . For a proof of (70), we have to show that

$$Cl(tr_{\mathbb{G}}(v)) \subseteq \{\varphi[\tau] \mid \varphi \in Cl(\mathbb{G}^{-})\},\$$

for every vertex v in V. To show this we make a case distinction. In case v = z, we have  $tr_{\mathbb{G}}(z) = \eta_z z \cdot tr_{\mathbb{G}^-}(z')$ , and so we find

$$Cl(\mathbf{tr}_{\mathbb{G}}(z)) = \{\mathbf{tr}_{\mathbb{G}}(z)\} \cup \{\varphi[\tau] \mid \varphi \in Cl(\mathbf{tr}_{\mathbb{G}^{-}}(z'))\}$$
(Proposition 2.44)  
$$\subseteq \{z[\tau]\} \cup \{\varphi[\tau] \mid \varphi \in Cl(\mathbf{tr}_{\mathbb{G}^{-}}(z'))\}$$
(obvious)  
$$\subseteq \{z[\tau]\} \cup \{\varphi[\tau] \mid \varphi \in Cl(\mathbb{G}^{-})\}$$
(definition  $Cl(\mathbb{G}^{-}))$   
$$\subseteq \{\varphi[\tau] \mid \varphi \in Cl(\mathbb{G}^{-})\}$$
( $z \in Cl(\mathbb{G}^{-})$ )

On the other hand, if  $v \neq z$ , we have  $\operatorname{tr}_{\mathbb{G}}(v) = \operatorname{tr}_{\mathbb{G}^-}(v)[\operatorname{tr}_{\mathbb{G}}(z)/z]$ , and so here we obtain

$$Cl(\operatorname{tr}_{\mathbb{G}}(v)) = \{\varphi[\tau] \mid \varphi \in Cl(\operatorname{tr}_{\mathbb{G}^{-}}(v))\} \cup Cl(\operatorname{tr}_{\mathbb{G}}(z))$$
(Proposition 2.44)  
$$= \{\varphi[\tau] \mid \varphi \in Cl(\mathbb{G}^{-})(v)\} \cup Cl(\operatorname{tr}_{\mathbb{G}}(z))$$
(definition  $Cl(\mathbb{G}^{-}))$   
$$\subseteq \{\varphi[\tau] \mid \varphi \in Cl(\mathbb{G}^{-})\}$$
(just proved)

6-26

Now that we have established (70), the remainder of the proof is straightforward:

$Cl(\mathbb{G}) \subseteq \{\varphi[\tau] \mid \varphi \in Cl(\mathbb{G}^-)\}$	(just proved)
$=\{\texttt{tr}_{\mathbb{G}^-}(v)[\tau]\mid v\in V\}$	(induction hypothesis)
$=\{\texttt{tr}_{\mathbb{G}}(v)\mid v\in V\}$	$(\text{definition } \mathtt{tr}_{\mathbb{G}})$

This suffices to prove the Claim.

The next claim states that the map  $tr_{\mathbb{G}}$  has the back-and-forth property; we leave its proof as an exercise for the reader.

CLAIM 2 Let v be some vertex in  $\mathbb{G}$ . Then the following hold:

1) if Evw then  $\operatorname{tr}_{\mathbb{G}}(v) \to_C \operatorname{tr}_{\mathbb{G}}(w)$ ;

2) if  $\operatorname{tr}_{\mathbb{G}}(v) \to_C \varphi$  then there is a vertex  $w \in V$  such that Evw and  $\operatorname{tr}_{\mathbb{G}}(w) = \varphi$ .

To establish the morphism conditions on the priority map we formulate the following claim.

CLAIM 3 The map  $tr_{\mathbb{G}}$  satisfies condition (4)) of Definition 6.18.

PROOF OF CLAIM It is immediate by the definitions that  $tr_{\mathbb{G}}(v)$  is a fixpoint formula whenever v is a *state* in  $\mathbb{G}$ , and that v and  $tr_{\mathbb{G}}(v)$  have the same parity. Given the definition of the parity formula  $\mathbb{G}_{\xi_{\mathbb{G}}}$ , it is left to show that

$$\Omega(v) < \Omega(w) \text{ iff } \operatorname{tr}_{\mathbb{G}}(v) \prec_C \operatorname{tr}_{\mathbb{G}}(w), \tag{71}$$

for any pair of states v, w of distinct parity that belong to the same cluster of  $\mathbb{G}$ . For the proof from left to right, the key observation is that  $\Omega(v) < \Omega(w)$  means that w is 'processed' later than v in the definition of  $\operatorname{tr}_{\mathbb{G}}$ , while v and w belonging to the same cluster implies that w is a free variable in  $\operatorname{tr}_{\mathbb{G}'}(v)$  for any intermediate-stage graph  $\mathbb{G}'$  in which  $\operatorname{tr}_{\mathbb{G}'}(v)$  has been defined already. Further details are left to the reader.

For the right-to-left direction of (71) we reason by contraposition. Suppose that  $\Omega(v) \not\leq \Omega(w)$ , then since v and w have different parity we must have  $\Omega(w) < \Omega(v)$ , so that by the left-to-right direction of (71) we find  $\operatorname{tr}_{\mathbb{G}}(w) \prec_C \operatorname{tr}_{\mathbb{G}}(v)$ . But then clearly we cannot have  $\operatorname{tr}_{\mathbb{G}}(v) \prec_C \operatorname{tr}_{\mathbb{G}}(w)$ .

Finally, since we have  $\operatorname{tr}_{\mathbb{G}}(v_I) = \xi_G$ , it is immediate by the definitions that the map  $\operatorname{tr}_{\mathbb{G}}$  satisfies condition (5)) of the definition or a parity formula morphism. QED

We now turn to the proof of the final item of Theorem 6.48.

**Proposition 6.54** For any parity formula  $\mathbb{G}$  and for any vertex v in  $\mathbb{G}$  we have  $\operatorname{ad}(\operatorname{tr}_{\mathbb{G}}(v)) \leq \operatorname{ind}(\mathbb{G})$ .

**Proof.** Let C be a cluster of  $\mathbb{G}$ , and let  $\eta$  be either  $\mu$  or  $\nu$ . An alternating  $\eta$ -chain in C of length k is a sequence  $v_1 \cdots v_k$  of states such that, for all i < k we have  $\Omega(v_i) < \Omega(v_k)$ , while  $v_i$  and  $v_{i+1}$  have different parities. We define  $\operatorname{acd}_{\Omega}^{\eta}(C)$  as the maximal length of such a chain, with  $\operatorname{acd}_{\Omega}^{\eta}(C) := 0$  if C has no such chains. Our key observation is the following claim.

•

CLAIM 1 Let d and  $\eta$  be such that  $\operatorname{acd}_{\Omega}^{\eta}(C) \leq d$  for every cluster C of  $\mathbb{G}$ . Then  $\operatorname{tr}_{\mathbb{G}}(v) \in \Theta_{d}^{\eta}$ .

PROOF OF CLAIM We prove the claim by induction on the weight  $(|\mathsf{Dom}(\Omega)|, |\mathbb{G}|)$  of  $\mathbb{G}$ . Let T be the top cluster of  $\mathbb{G}$ , and make a case distinction. We leave the case where T is transient as an exercise, and focus on the case where T is proper. Let, as in Definition 6.50, z be a state in T of maximal priority.

Let  $\mathbb{G}_T = (V, E_T, L_T, \Omega_T, v_I)$  be the parity formula given by  $E_T := E \cap (T \times V), L_T := L \upharpoonright_T \cup \{(u, u) \mid u \in V \setminus T\}$  and  $\Omega_T := \Omega \upharpoonright_T$ . In words,  $\mathbb{G}_T$  is the parity formula we obtain from  $\mathbb{G}$  by focusing on the top cluster T, replacing, for every vertex  $u \notin T$ , the generated subgraph  $G^u$  with the 'atomic' parity formula representing the atom u. It is not hard to see that, for all  $u \in V \setminus T$  we have

$$\operatorname{tr}_{\mathbb{G}}(u) = \operatorname{tr}_{\mathbb{G}^u}(u), \tag{72}$$

while the point of the construction is that for every  $t \in T$  we get:

$$\operatorname{tr}_{\mathbb{G}}(t) = \operatorname{tr}_{\mathbb{G}_{T}}(t)[\operatorname{tr}_{\mathbb{G}^{u}}(u)/u \mid u \in V \setminus T].$$
(73)

Now suppose that we can prove, for all  $t \in T$ , that

$$\operatorname{tr}_{\mathbb{G}_T}(t) \in \Theta_d^{\eta}. \tag{74}$$

Note that by the induction hypothesis, applied to the parity formulas  $\mathbb{G}^u$  with  $u \in V \setminus T$ , we have  $\operatorname{tr}_{\mathbb{G}^u}(u) \in \Theta_d^{\eta}$ . Then we may use clause (4) of Definition 2.50 to derive from (73) and (74) that  $\operatorname{tr}_{\mathbb{G}}(v) \in \Theta_d^{\eta}$  as required.

It is thus left to prove (74), and for this purpose we shall apply the induction hypothesis to the parity formula  $\mathbb{G}_T^-$ . Let  $\lambda$  be the parity of z. We will make use of the following relation between  $\mathtt{tr}_{\mathbb{G}}$  and  $\mathtt{tr}_{\mathbb{G}_T}$ , which is not hard to prove:

if 
$$\operatorname{\mathsf{Ran}}(\operatorname{tr}_{\mathbb{G}^{-}}) \subseteq \Theta_{e}^{\overline{\lambda}}$$
 then  $\operatorname{\mathsf{Ran}}(\operatorname{tr}_{\mathbb{G}}) \subseteq \Theta_{e}^{\overline{\lambda}}$ . (75)

Turning to the proof of (74), we make a case distinction, as to the nature of  $\lambda$ . Our reasoning will be slightly different in either case.

First consider the case where  $\lambda = \eta$ . This implies that every cluster D of  $\mathbb{G}_T^-$  satisfies  $ind_{\overline{\eta}}(D) \leq d-1$ . Then by the induction hypothesis we find that  $\operatorname{tr}_{\mathbb{G}_T^-}(v) \in \Theta_{d-1}^{\overline{\eta}}$ , for all  $v \in T$ . From this it follows by (75) that  $\operatorname{Ran}(\operatorname{tr}_{\mathbb{G}}) \subseteq \Theta_{d-1}^{\overline{\lambda}} = \Theta_{d-1}^{\overline{\eta}}$ , which means that we are done since  $\Theta_{d-1}^{\overline{\eta}} \subseteq \Theta_d^{\eta}$ .

If, on the other hand, we have  $\lambda = \overline{\eta}$ , then we reason as follows. Clearly, every cluster D of  $\mathbb{G}_T^-$  satisfies  $ind_{\eta}(D) \leq d$ . It follows by the induction hypothesis that  $\operatorname{tr}_{\mathbb{G}_T^-}(v) \in \Theta_d^{\eta}$ , for all  $v \in T$ . But then by (75) every formula of the form  $\operatorname{tr}_{\mathbb{G}_T}(t)$  belongs to  $\Theta_d^{\eta}$  as required.

Finally, it is not hard to derive the Proposition from Claim 1. With  $d := ind(\mathbb{G})$  and C a cluster of  $\mathbb{G}$ , one easily derives from the definitions that  $\operatorname{acd}_{\Omega}^{\mu}(C), \operatorname{acd}_{\Omega}^{\nu}(C) \leq d$ . From this it is immediate by the Claim that  $\operatorname{tr}_{\mathbb{G}}(v) \in \Theta_d^{\mu} \cap \Theta_d^{\nu}$ , for any v in  $\mathbb{G}$ . From this we obtain  $\operatorname{ad}(\operatorname{tr}_{\mathbb{G}}(v)) \leq d$  as required. QED

**Proof of Theorem 6.48.** First let  $\mathbb{G}$  be an arbitrary balanced parity formula. By Proposition 6.53 and Theorem 6.38 we find that, respectively,  $\mathbb{G} \equiv \mathbb{G}_{\xi_{\mathbb{G}}}$  and  $\mathbb{G}_{\xi_{\mathbb{G}}} \equiv \xi_{\mathbb{G}}$ . From this it is immediate that  $\mathbb{G} \equiv \xi_{\mathbb{G}}$ . Furthermore, it follows from Claim 1 in the proof of Proposition 6.53 that  $|\xi_{\mathbb{G}}| \leq |\mathbb{G}|$ , and from Proposition 6.54 that  $\mathsf{ad}(\mathsf{tr}_{\mathbb{G}}(v)) \leq ind(\mathbb{G})$ .

From this and the definition of  $\xi_{\mathbb{G}}$  the Theorem is immediate.

The construction of the Definitions 6.50 and 6.52 provides, for every parity formula  $\mathbb{G}$ , an equivalent formula  $\xi_{\mathbb{G}}$  of size *linear* in the size of  $\mathbb{G}$ , at least, if we define the size of  $\xi_{\mathbb{G}}$  as it *closure-size*. If we measure  $\xi_{\mathbb{G}}$  by its number of subformulas, the best upper bound that we can obtain is *exponential*, see Exercise 6.2. (Note that we cannot state that the *subformula-size* of  $\operatorname{tr}_{\mathbb{G}}$  is at most exponential in the size of  $\mathbb{G}$  since the formula  $\xi_{\mathbb{G}}$  will generally not be clean, and so its subformula-size may not be defined.)

The next proposition reveals that the translation given in Definition 6.50 may actually produce formulas with exponentially many subformulas, relative to the size of the parity formula. The 'culprit' here is the application of the substitution operation in the inductive step of the definition, since this may double the number of subformulas each time it is applied. The proposition thus provides an example witnessing that the closure size of a formula can be *exponentially* smaller than its number of subformulas.

**Proposition 6.55** There is a family  $(\mathbb{F}_n)_{n\in\omega}$  such that for every *n* it holds that  $|\mathbb{F}_n| \leq 2n+2$ , which implies that  $|\xi_{\mathbb{F}_n}|$  is linear in *n*, while  $|Sf(\xi_n)| \geq 2^n$ .

**Proof.** For some arbitrary but fixed number n, consider the parity formula  $\mathbb{F} = (V, E, L, \Omega, v_I)$  given by

$$\begin{array}{rcl} V & := & \{s_i, v_i \mid 0 \le i \le n\} \\ E & := & \{(s_i, v_i) \mid 0 \le i \le n\} \cup \{(s_{i+1}, s_i) \mid 0 \le i \le n-1\} \\ & \cup \{(v_0, s_n)\} \cup \{(v_i, s_i) \mid 0 < i \le n\} \\ L & := & \{(s_i, \wedge), (v_i, \diamond) \mid 0 \le i \le n\} \\ \Omega & := & \{(v_i, i) \mid 0 \le i \le n\} \\ v_I & := & v_0. \end{array}$$

In Figure 10 we display a picture of the parity formula  $\mathbb{F}$ , for n = 4.

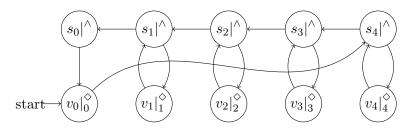

Figure 10: the parity formula  $\mathbb{F}$ 

Our claim is that

$$|Sf(\operatorname{tr}_{\mathbb{F}}(v_0))| \ge 2^n,\tag{76}$$

QED

and in order to prove (76), we will use the notion of *fixpoint depth* of a formula. Recall that we define  $fd(\varphi) := 0$  if  $\varphi$  is atomic,  $fd(\varphi_0 \odot \varphi_1) := \max(fd(\varphi_0), fd(\varphi_1)), fd(\heartsuit \varphi) := fd(\varphi)$ , and  $fd(\eta x.\varphi) := 1 + fd(\varphi)$ . It is an easy exercise to verify that any  $\mu$ -calculus formula  $\xi$  satisfies  $|Sf(\xi)| \ge fd(\xi)$ , so that, in order to prove (76), it suffices to show that

$$fd(\operatorname{tr}_{\mathbb{F}}(v_0)) \ge 2^n. \tag{77}$$

To calculate  $\operatorname{tr}_{\mathbb{F}}(v_0)$  it will be useful to introduce some auxiliary structures. For  $k \in [0, n]$ , we let  $\mathbb{F}_k$  denote the formula  $(V_k, E_k, L_k, \Omega_k, s)$  given by

$$\begin{array}{rcl} V_k & := & V \cup \{u_i \mid k \le i \le n\} \\ E_k & := & \{(s_i, v_i) \mid 0 \le i < k\} \cup \{(s_j, u_j) \mid k \le j \le n\} \cup \{(s_{i+1}, s_i) \mid 0 \le i \le n-1\} \\ & \cup \{(v_0, s_n)\} \cup \{(v_i, s_i) \mid 0 < i \le n\} \\ L_k & := & L \cup \{(u_j, v_j) \mid k \le j \le n\} \\ \Omega_k & := & \{(v_i, i) \mid 0 \le i \le k\} \end{array}$$

For an example, see Figure 11, which contains a picture of the formula  $\mathbb{F}_2$  in the case where n = 4. Using the notation of Definition 6.50 (but writing  $u_i$  for  $v_i^*$ ), we have  $\mathbb{F} = \mathbb{F}_n$ 

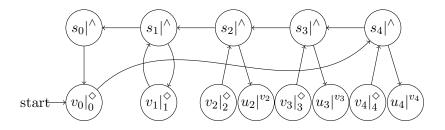

Figure 11: the parity formula  $\mathbb{F}_2$ 

and  $\mathbb{F}_{k+1}^{-} = \mathbb{F}_k$ , for all  $k \in [0, n-1]$ .

We now turn to the translation maps associated with these parity formulas. Observe that it follows from the definitions that  $M_{\mathbb{F}_k} = \{v_k\}$ , so that we obtain the following definitions (where to avoid clutter we write  $tr_k$  rather than  $tr_{\mathbb{F}_k}$ , and omit brackets in conjunctions):

 $\begin{array}{lll} \operatorname{tr}_0(v_0) & := & \diamond \bigwedge_{0 \leq i \leq n} v_i \\ \operatorname{tr}_0(v_m) & := & \diamond \bigwedge_{0 \leq i \leq m} v_i & \text{ for all } m \in [1, n] \\ \operatorname{tr}_{k+1}(v_k) & := & \eta_k v_k \cdot \operatorname{tr}_k(v_k) & \text{ for all } k \in [0, n] \\ \operatorname{tr}_{k+1}(v_\ell) & := & \operatorname{tr}_k(v_\ell)[\operatorname{tr}_{k+1}(v_k)/v_k] & \text{ for all } k \in [0, n] \text{ and all } \ell \neq k) \end{array}$ 

In order to prove (76), we need an auxiliary notion of (relative) fixpoint depth. Given a formula  $\varphi$  and variable x, we let  $fd(x, \varphi)$ , the *fixpoint depth of* x in  $\varphi$ , denote the maximum number of fixpoint operators that one may meet on a path from the root of the syntax tree of  $\varphi$  to a free occurrence of x in  $\varphi$ , with  $fd(x, \varphi) = -\infty$  if no such occurrence exists. Formally,

we set

$$\begin{aligned} fd(x,\varphi) &:= \begin{cases} 0 & \text{if } \varphi = x \\ -\infty & \text{if } \varphi \text{ is atomic, but } \varphi \neq x \end{cases} \\ fd(x,\varphi_0 \odot \varphi_1) &:= & \max\left(fd(x,\varphi_0), fd(x,\varphi_1)\right) & \text{where } \odot \in \{\wedge,\vee\} \\ fd(x,\nabla\varphi) &:= & fd(x,\varphi) & \text{where } \nabla \in \{\diamond,\Box\} \\ fd(x,\eta y.\varphi) &:= & \begin{cases} -\infty & \text{if } x = y \\ 1 + fd(x,\varphi) & \text{if } x \neq y \end{cases} & \text{where } \eta \in \{\mu,\nu\} \end{aligned}$$

Without proof we mention that, provided  $x \neq y$  and y is free for y in  $\varphi$ :

$$fd(x,\varphi[\psi/y]) = \max\left(fd(x,\varphi), fd(y,\varphi) + fd(x,\psi)\right).$$

From this we immediately infer that

$$fd(x,\varphi[\psi/y]) \ge fd(y,\varphi) + fd(x,\psi), \tag{78}$$

which is in fact the crucial observation in the proof: here we see that the translation doubles the fixpoint depth of the formulas in every step.

CLAIM 1 For all  $k \in [1, n]$ , and all  $\ell, m \ge k$  we have that  $fd(v_{\ell}, tr_k(v_m)) \ge 2^k - 1$ .

PROOF OF CLAIM We prove the claim by induction on k. For the base step of the induction, where k = 1, it suffices to observe that  $fd(v_{\ell}, \operatorname{tr}_1(v_m)) = 1$ , for all  $\ell, m \ge 1$ . But this is obvious by the observation that for all  $m \ge 1$  we may calculate  $\operatorname{tr}_1(v_m) = \diamond (\nu v_0 . \diamond \bigwedge_{0 \le i \le n} v_i) \land \bigwedge_{1 \le i \le \ell} v_i$ .

For the induction step, we consider the case for k + 1. Taking arbitrary numbers  $\ell, m \ge k + 1$ , we reason as follows:

$$\begin{aligned} fd(v_{\ell}, \mathtt{tr}_{k+1}(v_m)) &= fd(v_{\ell}, \mathtt{tr}_k(v_m)[\mathtt{tr}_{k+1}(v_k)/v_k]) & (\text{definition } \mathtt{tr}_{k+1}(v_m)) \\ &\geq fd(v_k, \mathtt{tr}_k(v_m)) + fd(v_{\ell}, \mathtt{tr}_{k+1}(v_k)) & (\text{equation } (78)) \\ &= fd(v_k, \mathtt{tr}_k(v_m)) + fd(v_{\ell}, \eta_k v_k. \mathtt{tr}_k(v_k))) & (\text{definition } \mathtt{tr}_{k+1}(v_k)) \\ &\geq fd(v_k, \mathtt{tr}_k(v_m)) + 1 + fd(v_{\ell}, \mathtt{tr}_k(v_k))) & (\text{definition } fd(\cdot), \ell > k) \\ &\geq (2^k - 1) + 1 + (2^k - 1) & (\text{induction hypothesis, twice}) \\ &= 2^{k+1} - 1. \end{aligned}$$

Clearly this finishes the proof of the claim.

Finally, it is easy to see how (77) follows from the Claim. QED

**Exercise 6.2** Let  $\mathbb{G}$  be an arbitrary balanced parity formula. Prove that the number of subformulas of  $\xi_{\mathbb{G}}$  is at most exponential in the size of  $\mathbb{G}$ .

◄

#### 6.5 Alternation depth

in Chapter 2 we formally defined the notion of alternation depth by means of an inductive definition. We also mentioned that, intuitively, the alternation depth corresponds to the maximal length of certain alternating chains. In this section we will make this relation precise by proving the following results:

If ξ is clean, then its alternation depth corresponds to the maximal length of an alternating chain of bound variables of ξ that are ordered by the dependency order ≼<sub>ξ</sub>:

$$\operatorname{ad}(\xi) = \operatorname{acd}(\preccurlyeq_{\xi}).$$
 (79)

 if ξ is tidy, then its alternation depth corresponds to the maximal length of an alternating chain of fixpoint formulas in Cl(ξ) that are ordered by the closure priority order ≼<sub>C</sub>:

$$\mathsf{ad}(\xi) = \mathsf{acd}(\preccurlyeq_C \restriction_{\mathcal{E}}). \tag{80}$$

Unfortunately the proofs of these results are rather finicky, especially the one of (80).

First of all, we need to refine some of our earlier definitions on alternating chains.

**Definition 6.56** Let  $\mathbb{Z} = (Z, \preccurlyeq, p)$  be some parity preorder, and let  $\vec{z} = z_1 \cdots z_k$  be some alternating chain in  $\mathbb{Z}$ . We call  $\vec{z}$  a  $\mu$ -chain if  $p(z_k) = 1$ , and a  $\nu$ -chain if  $p(z_k) = 0$ .

For  $\eta \in \{\mu, \nu\}$  we define the *alternating*  $\eta$ -*depth*  $\operatorname{acd}_{\eta}(\mathbb{Z})$  of  $\mathbb{Z}$  as the maximal length of an alternating  $\eta$ -chain in  $\mathbb{Z}$ .

Clearly then we have  $\operatorname{acd}(\preccurlyeq) = \max(\operatorname{acd}_{\mu}(\preccurlyeq), \operatorname{acd}_{\nu}(\preccurlyeq))$ . Note as well that if  $\mathbb{Z}$  has no states of odd (even) parity, then we set  $\operatorname{acd}_{\mu}(\preccurlyeq) = 0$  ( $\operatorname{acd}_{\nu}(\preccurlyeq) = 0$ , respectively).

For an intuitive understanding of the following technical observation, recall that clause (4) of Definition 2.50 states that the classes  $\Theta_n^{\eta}$  are closed under substitution. Proposition 6.57 states a kind of converse to this. We leave the proof of this result as an exercise for the reader.

**Proposition 6.57** Let  $\xi$  and  $\chi$  be  $\mu$ -calculus formulas such that  $\xi$  is free for x in  $\chi$ . If  $\chi[\xi/x] \in \Theta_k^{\eta}$  then  $\chi \in \Theta_k^{\eta}$ . Furthermore, if  $x \in FV(\chi)$  then we also have  $\xi \in \Theta_k^{\eta}$ .

In the case of a *clean* formula there is a simple characterisation of alternation depth, linking it to the length of alternating chains of the dependency order  $\preccurlyeq_{\xi}$  on the bound variables of  $\xi$ .

**Proposition 6.58** Let  $\xi$  be a clean formula. Then for any  $k \in \omega$  and  $\eta \in \{\mu, \nu\}$  we have

$$\xi \in \Theta_k^\eta \text{ iff } \operatorname{acd}_\eta(\preccurlyeq_\xi) \le k, \tag{81}$$

As a corollary, the alternation depth of  $\xi$  is equal to the length of its longest alternating dependency chain.

One of the key insights in the proof of this Proposition is that, with  $\psi$  free for x in  $\varphi$ , any dependency chain in  $\varphi[\psi/x]$  originates entirely from either  $\varphi$  or  $\psi$ . Recall from Definition 2.2 that we write  $\overline{\mu} = \nu$  and  $\overline{\nu} = \mu$ .

**Proof of Proposition 6.58.** For the sake of a concise notation we will write  $d_{\eta}(\xi) := \operatorname{acd}_{\eta}(\prec_{\xi})$ .

We prove the implication from left to right in (81) by induction on the derivation that  $\xi \in \Theta_k^{\eta}$ . In the base step of this induction (corresponding to clause (1) in the definition of alternation depth)  $\xi$  is atomic, so that we immediately find  $d_{\eta}(\xi) = 0$  as required.

In the induction step of the proof, we make a case distinction as to the last applied clause in the derivation of  $\xi \in \Theta_k^{\eta}$ , and we leave the (easy) cases, where this clause was either (2) or (3), for the reader.

Suppose then that  $\xi \in \Theta_k^{\eta}$  on the basis of clause (4). In this case we find that  $\xi = \xi'[\psi/z]$  for some formulas  $\xi', \psi$  such that  $\psi$  is free for z in  $\xi'$  and  $\xi', \psi \in \Theta_k^{\eta}$ . By the 'key insight' mentioned right after the formulation of the Proposition, any  $\eta$ -chain in the formula  $\xi$  is a  $\eta$ -chain in either  $\xi'$  or  $\psi$ . But then by the induction hypothesis it follows that the length of any such chain must be bounded by k.

Finally, consider the case where  $\xi \in \Theta_k^{\eta}$  on the basis of clause (5). We make a further case distinction. If  $\xi \in \Theta_{k-1}^{\eta}$ , then by the induction hypothesis we may conclude that  $d_{\eta}(\xi) \leq k-1$ , and from this it is immediate that  $d_{\eta}(\xi) \leq k$ . If, on the other hand,  $\xi \in \Theta_{k-1}^{\overline{\eta}}$  then the induction hypothesis yields  $d_{\overline{\eta}}(\xi) \leq k-1$ . But since  $d_{\eta}(\xi) \leq d_{\overline{\eta}}(\xi) + 1$  we obtain  $d_{\eta}(\xi) \leq k$  indeed.

The opposite, right-to-left, implication in (81) is proved by induction on k. In the base step of this induction we have  $d_{\eta}(\xi) = 0$ , which means that  $\xi$  has no  $\eta$ -variables; from this it is easy to derive that  $\xi \in \Theta_0^{\eta}$ .

For the induction step, we assume as our induction hypothesis that (81) holds for  $k \in \omega$ , and we set out to prove the same statement for k + 1 and an arbitrary  $\eta \in \{\mu, \nu\}$ :

if 
$$d_{\eta}(\xi) \le k+1$$
 then  $\xi \in \Theta_{k+1}^{\eta}$ . (82)

We will prove (82) by an 'inner' induction on the length of  $\xi$ . The base step of this inner induction is easy to deal with: if  $|\xi|^{\ell} = 1$  then  $\xi$  must be atomic so that certainly  $\xi \in \Theta_{k+1}^{\eta}$ .

In the induction step we are considering a formula  $\xi$  with  $|\xi|^{\ell} > 1$ . Assume that  $d_{\eta}(\xi) \leq k+1$ . We make a case distinction as to the shape of  $\xi$ . The only case of interest is where  $\xi$  is a fixpoint formula, say,  $\xi = \eta x \cdot \chi$  or  $\xi = \overline{\eta} x \cdot \chi$ . If  $\xi = \overline{\eta} x \cdot \chi$ , then obviously we have  $d_{\eta}(\xi) = \delta_{\eta}(\chi)$ , so by the inner induction hypothesis we find  $\chi \in \Theta_{k+1}^{\eta}$ . From this we immediately derive that  $\xi = \overline{\eta} x \cdot \chi \in \Theta_{k+1}^{\eta}$  as well.

Alternatively, if  $\xi = \eta x \cdot \chi$ , we split further into cases: If  $\chi$  has an  $\overline{\eta}$ -chain  $y_1 \cdots y_{k+1}$  of length k + 1, then obviously we have  $x \notin FV(\delta_{k+1})$  (where we write  $\delta_{k+1}$  instead of  $\delta_{y_{k+1}}$ ), for otherwise we would get  $x >_{\xi} y_{k+1}$ , so that we could add x to the  $\overline{\eta}$ -chain  $y_1 \cdots y_{k+1}$  and obtain an  $\eta$ -chain  $y_1 \cdots y_{k+1}x$  of length k + 2. But if  $x \notin FV(\delta_{k+1})$  we may take some fresh variable z and write  $\xi = \xi'[\overline{\eta}y_{k+1}.\delta_{k+1}/z]$  for some formula  $\xi'$  where the formula  $\overline{\eta}y_{k+1}.\delta_{k+1}$ is free for z. By our inner induction hypothesis we find that both  $\xi'$  and  $\eta y_{k+1}.\delta_{k+1}$  belong to  $\Theta_{k+1}^{\eta}$ . But then by clause (4) of Definition 2.50 the formula  $\xi$  also belongs to the set  $\Theta_{k+1}^{\eta}$ .

If, on the other hand,  $\chi$  has  $no \ \overline{\eta}$ -chain of length k + 1, then we clearly have  $d_{\overline{\eta}}(\chi) \leq k$ . Using the outer induction hypothesis we infer  $\chi \in \Theta_k^{\overline{\eta}}$ , and so by clause (3) of Definition 2.50 we also find  $\xi = \eta x \cdot \chi \in \Theta_k^{\overline{\eta}}$ . Finally then, clause (5) gives  $\xi \in \Theta_{k+1}^{\eta}$ . QED Turning to the analogous result for tidy formulas, we need some further auxiliary results. The first of these states that, when analysing the alternation depth of a tidy formula of the form  $\chi[\xi/x]$ , we may without loss of generality assume that  $\xi$  is not a free subformula of  $\chi$ .

**Proposition 6.59** Let  $\xi$  and  $\chi$  be  $\mu$ -calculus formulas such that  $\xi$  is free for x in  $\chi$ ,  $x \in FV(\chi)$ ,  $|\xi|^{\ell} > 1$ , and  $\chi[\xi/x]$  is tidy. Then there is a tidy formula  $\chi'$  such that  $\xi$  is free for x' in  $\chi'$ ,  $\chi'[\xi/x'] = \chi[\xi/x]$ ,  $|\chi'|^{\ell} \le |\chi|^{\ell}$ ,  $\mathsf{ad}_{\eta}(\chi') \le \mathsf{ad}_{\eta}(\chi)$  for  $\eta \in \{\mu, \nu\}$ , and  $\xi \not \le f \chi'$ .

**Proof.** The proof proceeds by induction on the length of  $\chi$ . In case  $\xi \not \leq_f \chi$  we are done immediately, since then we can simply take  $\chi' := \chi$ . We will therefore assume that  $\xi \leq_f \chi$ . Then by definition we have  $\chi = \varphi[\xi/y]$  for some tidy formula  $\varphi$  such that  $y \in FV(\chi)$  and  $\xi$ is free for y in  $\varphi$ . Since  $|\xi|^{\ell} > 1$  we find that  $|\varphi|^{\ell} < |\chi|^{\ell}$ , and so we may apply the induction hypothesis to  $\varphi$ . That means that we can find a tidy formula  $\varphi'$  such that  $\chi = \varphi'[\xi/y']$  for some variable  $y \in FV(\varphi')$ ,  $\xi$  is free for y' in  $\varphi'$ ,  $|\varphi'|^{\ell} \leq |\varphi|^{\ell}$ ,  $\mathrm{ad}_{\eta}(\varphi') \leq \mathrm{ad}_{\eta}(\varphi)$  and  $\xi \not \leq_f \varphi'$ . Now define  $\chi' := \varphi'[x'/x, x'/y']$ , for some fresh variable x'. Then clearly we have that

Now define  $\chi' := \varphi' [x'/x, x'/y']$ , for some fresh variable x'. Then clearly we have that  $|\chi'|^{\ell} = |\varphi'|^{\ell} \le |\varphi|^{\ell} < |\chi|^{\ell}$  and  $\operatorname{ad}_{\eta}(\chi') = \operatorname{ad}_{\eta}(\varphi') \le \operatorname{ad}_{\eta}(\varphi) \le \operatorname{ad}_{\eta}(\chi)$ , where the last inequality follows from Proposition 6.57 and the fact that  $\chi = \varphi[\xi/y]$ . We leave it for the reader to convince themselves that  $\xi \not \ll_f \varphi'$  entails  $\xi \not \ll_f \chi'$ . Finally, it is not hard to verify that  $\chi'[\xi/x'] = \varphi'[x'/x, x'/y'][\xi/x'] = \varphi'[\xi/y'][\xi/x] = \chi[\xi/x]$  as required. QED

Our main auxiliary proposition concerns the relation between parity formulas of the form  $\mathbb{G}_{\chi}$  and  $\mathbb{G}_{\chi[\xi/x]}$ , respectively. Roughly, it states that under some mild conditions, the substitution  $\xi/x$  is a 'local isomorphism' between these two structures, i.e., an isomorphism at the level of certain clusters. Recall that  $\langle\!\psi\rangle\!\rangle_C$  denotes the  $\equiv_C$ -cluster of a formula  $\psi$ .

**Proposition 6.60 (substitution as local isomorphism)** Let  $\xi$  and  $\chi$  be formulas such that  $\xi$  is free for x in  $\chi$  and  $\chi[\xi/x]$  is tidy. Furthermore, assume that  $\xi \notin Cl(\chi)$ , and  $x \notin FV(\xi)$ . Then the following hold:

- 1) the substitution  $\xi/x : Cl(\chi) \to Cl(\chi[\xi/x])$  is injective;
- 2) if  $\psi \in Cl(\chi)$  is such that  $\psi[\xi/x] \notin Cl(\chi) \cup Cl(\xi)$ , then  $\xi/x$  is an isomorphism between the structures  $(\langle\!\!\langle \psi \rangle\!\!\rangle_C, L_C, \to_C, \triangleleft_f, \preccurlyeq_C)$  and  $(\langle\!\!\langle \psi |\!\!\langle \xi/x |\!\!\rangle_C, L_C, \to_C, \triangleleft_f, \preccurlyeq_C)$ .

We omit the proof of this Proposition, which is similar to that of Proposition 6.46.

**Proposition 6.61** For any tidy formula  $\xi$  and  $\eta \in {\mu, \nu}$ , we have

$$cd_{\eta}(\xi) \le n \quad iff \ \xi \in \Theta_n^{\eta}.$$
 (83)

As a corollary, the alternation depth of  $\xi$  is equal to the length of its longest alternating  $\prec_C$ -chain.

**Proof.** In this proof we shall be reasoning about the clusterwise ordering of fixpoints formulas, and so the following notation will be handy. Given a closure cluster D of  $\xi$  we let, for  $\eta \in {\mu, \nu}, cd_{\eta}(D) := \operatorname{acd}_{\eta}(\prec_C \upharpoonright_D)$  denote the maximal length of an alternating  $\prec_C$ -chain in Dleading up to an  $\eta$ -formula, and similarly we write  $cd(D) := \operatorname{acd}(\prec_C \upharpoonright_D)$  and  $cd(\xi) := \operatorname{acd}(\prec_C \upharpoonright_{\xi})$ . Clearly then we have  $cd(C) = \max(cd_{\mu}(C), cd_{\nu}(C)), cd(\xi) = \max(cd_{\mu}(\xi), cd_{\nu}(\xi))$ , etc. For the proof of the left-to-right direction of (83), we proceed by an outer induction on n, and an inner induction on the length  $|\xi|^{\ell}$  of the formula  $\xi$ . We focus on the outer inductive case, leaving the base case, where n = 0, to the reader.

First of all, it is easy to see that every fixpoint formula  $\xi'$  in the cluster of  $\xi$  satisfies  $cd_{\eta}(\xi') = cd_{\eta}(\xi)$ , while it follows from Proposition 2.54 that  $\xi' \in \Theta_n^{\eta}$  iff  $\xi \in \Theta_n^{\eta}$ . For this • reason we may, without loss of generality, confine our attention to the case where  $\xi$  is the  $\prec_C$ -maximal element of its cluster. This means that  $\xi$  is a fixpoint formula, and so we may distinguish cases, as to its parity.

First we consider the case where  $\xi$  is of the form  $\xi = \overline{\eta} x \cdot \chi$ . Let

$$\eta_1 x_1.\psi_1 \prec_C \eta_2 x_2.\psi_2 \prec_C \cdots \prec_C \eta_k x_k.\psi_k$$

be a maximal alternating  $\eta$ -chain in  $Cl(\chi)$ . Then

$$\eta_1 x_1 \psi_1[\xi/x] \prec_C \eta_2 x_2 \psi_2[\xi/x] \prec_C \cdots \prec_C \eta_k x_k \psi_k[\xi/x]$$

is an alternating  $\eta$ -chain in  $Cl(\xi)$ , and so we have  $k \leq n$ . It then follows by the inner induction hypothesis that  $\chi \in \Theta_n^{\eta}$ , and so by definition of the latter set we find  $\xi = \overline{\eta}x.\chi \in \Theta_n^{\eta}$ , as required.

The other case to be discussed is where  $\xi$  is of the form  $\xi = \eta x \cdot \chi$ . Now let

$$\eta_1 x_1.\psi_1 \prec_C \eta_2 x_2.\psi_2 \prec_C \cdots \prec_C \eta_k x_k.\psi_k$$

be a maximal alternating  $\overline{\eta}$ -chain in  $Cl(\chi)$ .

We now make a further case distinction. If x is a free variable of some formula in this chain, it is in fact a free variable of every formula in the chain; from this it follows that

$$\eta_1 x_1 \cdot \psi_1[\xi/x] \prec_C \eta_2 x_2 \cdot \psi_2[\xi/x] \prec_C \cdots \prec_C \eta_k x_k \cdot \psi_k[\xi/x] \prec_C \xi$$

is an alternating  $\eta$ -chain in the cluster  $(\xi)_C$  of  $\xi$ . Since this chain has length k + 1, it follows by our assumption on  $\xi$  that  $k + 1 \leq n$ , and so  $k \leq n - 1$ . Alternatively, if x is not a free variable of any formula in this chain, then the chain is itself an alternating  $\overline{\eta}$ -chain in  $Cl(\xi)$ , and from this and the assumption that  $cd_{\eta}(\xi) \leq n$  it readily follows that  $k \leq n - 1$ .

In both cases we find that  $k \leq n-1$ , which means that  $cd_{\overline{\eta}}(\chi) \leq n-1$ . By the outer induction hypothesis we thus find that  $\chi \in \Theta_{n-1}^{\overline{\eta}}$ . From this it is then easy to derive that  $\xi = \eta x \cdot \chi \in \Theta_n^{\eta}$ .

For a proof of the opposite, right-to-left direction ' $\Leftarrow$ ' of (83), the argument proceeds by induction on the length of  $\varphi$ . In the base case  $\varphi$  is atomic and hence the claim is trivially true.

In the inductive step we make a case distinction depending on the clause of Definition 2.50 that was applied in the last step of the derivation of  $\varphi \in \Theta_k^{\eta}$ . We leave the easy cases, for the clauses 1 and 2, to the reader.

If clause 3 is used to derive  $\varphi \in \Theta_n^{\eta}$  then  $\varphi = \overline{\eta}x.\chi$  for some  $\chi \in \Theta_n^{\eta}$ . First define  $\chi' = \chi[x'/x]$  for an x' that is fresh for  $\chi$  and  $\varphi$ . Note that the length of  $\chi'$  is equal to the length of  $\chi$ , which is shorter than the length of  $\varphi$ . By Proposition 6.57 we also have that

 $\chi' \in \Theta_n^{\eta}$ . Moreover,  $\chi'$  is tidy because  $\varphi$  is tidy,  $BV(\chi') = BV(\chi) \subseteq BV(\varphi)$ ,  $FV(\chi') = (FV(\chi) \setminus \{x\}) \cup \{x'\} \subseteq FV(\varphi) \cup \{x'\}$ , and x' is fresh for  $\varphi$ . This means that we can apply the inductive hypothesis to  $\chi'$ , obtaining that  $cd_n(\chi') \leq n$ 

We then distinguish cases depending on whether  $\varphi \in Cl(\chi)$  or not.

If  $\varphi \in Cl(\chi)$  then it is not hard to prove that  $\varphi \in Cl(\chi')$  as well. It is then easy to see that every alternating chain in  $\mathbb{G}_{\varphi}$  also exists in  $\mathbb{G}_{\chi'}$ , and thus it follows that  $cd_{\eta}(\varphi) \leq n$ .

If  $\varphi \notin Cl(\chi)$  we distinguish further cases depending on whether  $x \in FV(\chi)$ . If this is not the case then  $\chi' = \chi$  and  $\mathbb{G}_{\varphi}$  is just like  $\mathbb{G}_{\chi}$  with an additional vertex for  $\varphi$  that forms a transient cluster on its own and is connected just with an outgoing  $\to_C$ -edge to the vertex of  $\chi'$  in  $\mathbb{G}_{\chi'}$ . Thus, every alternating chain in a cluster of  $\mathbb{G}_{\varphi}$  also exists in  $\mathbb{G}_{\chi'}$  and thus  $cd_{\eta}(\varphi) \leq n$  follows from  $cd_{\eta}(\chi') \leq n$ .

The last case is where  $\varphi \notin Cl(\chi)$  and  $x \in FV(\chi)$ . To prove  $cd_{\eta}(\varphi) \leq n$  consider an alternating  $\prec_C$ -chain  $\eta_1 x_1 . \rho_1 \prec_C \cdots \prec_C \eta_m x_m . \rho_m$ , of length m and with  $\eta_m = \eta$  in some cluster of  $\mathbb{G}_{\varphi}$ . We now argue that  $m \leq n$ . Because  $\eta_i x_i . \rho_i \in Cl(\varphi)$  for all  $i \in [1, m]$  it follows by Proposition 6.42(4) that the only possibility for  $\varphi$  to be among the  $\eta_i x_i . \rho_i$  in this chain is if  $\varphi = \eta_m x_m . \rho_m$ . This would lead to a contradiction however, because  $\eta_m = \eta$  while we assumed that  $\varphi = \overline{\eta} x. \chi$ . We may therefore conclude that  $\varphi$  is not among the  $\eta_i x_i . \rho_i$  for  $i \in [1, m]$ . By the items 1), 3) and 5) of Proposition 6.46 it follows that there is an alternating  $\prec_C$ -chain  $\eta_1 x_1 . \sigma_1 \prec_C \cdots \prec_C \eta_m x_m . \sigma_m$  in  $Cl(\chi')$  such that  $(\eta_i x_i . \sigma_i)[\xi/x'] = \eta_i x_i . \rho_i$  for all  $i \in [1, m]$ . Because  $cd_{\eta}(\chi') \leq n$  it follows that  $m \leq n$ .

If clause 4 is used to derive  $\varphi \in \Theta_n^{\eta}$  then  $\varphi$  is of the form  $\varphi = \chi[\xi/x]$  such that  $\chi, \xi \in \Theta_n^{\eta}$ . First observe that we may assume that  $x \in FV(\chi)$  and  $|\xi|^{\ell} > 1$ , otherwise the claim trivialises. Furthermore, because of Proposition 6.59 we may without loss of generality assume that in addition  $\chi$  is tidy as well, that x is fresh for  $\xi$ , and that  $\xi \not \ll_f \chi$ . Finally, since  $|\xi|^{\ell} > 1$  we find that the length of  $\chi$  is smaller than that of  $\varphi = \chi[\xi/x]$ , so that we may apply the inductive hypothesis, which gives that  $cd_{\eta}(\chi) \leq n$  and  $cd_{\eta}(\xi) \leq n$ .

To show that  $cd_{\eta}(\chi[\xi/x]) \leq n$  consider a fixpoint formula  $\eta y.\rho \in Cl(\chi[\xi/x])$  that is at the top of a maximal alternating  $\prec_C$ -chain in  $\mathbb{G}_{\chi[\xi/x]}$ . Recall from Definition 6.32 that  $h^{\downarrow}(\eta y.\rho)$  denotes the maximal length of an alternating  $\prec_C$ -chain leading up to  $\eta y.\rho$ . In order to show that  $h^{\downarrow}(\eta y.\rho) \leq n$ , we claim that

$$h^{\downarrow}(\eta y.\rho) = h^{\downarrow}(\eta y.\rho') \text{ for some } \eta y.\rho' \in Cl(\chi) \cup Cl(\xi).$$
(84)

To see this, first note that we may assume that  $\eta y.\rho \notin Cl(\chi) \cup Cl(\xi)$  because otherwise we can just set  $\rho' := \rho$ . By Proposition 2.44 we obtain that

$$Cl(\chi[\xi/x]) = \{ \psi[\xi/x] \mid \psi \in Cl(\chi) \} \cup Cl(\xi).$$

Therefore, since  $\eta y.\rho \in Cl(\chi[\xi/x])$ , and we assume that  $\eta y.\rho \notin Cl(\xi)$ , it follows that  $\eta y.\rho = \psi[\xi/x]$  for some  $\psi \in Cl(\chi)$ . We are thus in a position to apply Proposition 6.60, which describes how the  $\rightarrow_C$ -cluster of  $\psi$  relates under the substitution  $\xi/x$  to the  $\rightarrow_C$ -cluster of  $\eta y.\rho = \psi[\xi/x]$ . Note that  $\psi \neq x$  because otherwise we would have  $\eta y.\rho = \xi$ , contradicting the assumption that  $\eta x.\rho \notin Cl(\xi)$ . This means that  $\psi = \eta y.\rho'$  for some formula  $\rho'$ , since the substitution  $\xi/x$  preserves the main connective of formulas other than x. Finally, it follows from item 2) of Proposition 6.60 that  $h^{\downarrow}(\eta y.\rho) = h^{\downarrow}(\eta y.\rho')$ .

As an immediate consequence of (84) we obtain that  $h^{\downarrow}(\eta y.\rho') \leq n$  because  $\eta y.\rho'$  is either in  $\mathbb{G}_{\chi}$  or in  $\mathbb{G}_{\xi}$ , where the inductive hypothesis applies. This finishes the proof for the case of clause 4.

We leave the last case, where clause 5 is used to derive that  $\varphi \in \Theta_n^{\eta}$ , to the reader. QED

## 6.6 Guarded transformation

As an example of an important construction on parity formulas, we consider the operation of guarded transformation. Recall from Definition 2.19 that a  $\mu$ -calculus formula is *guarded* if every occurrence of a bound variable is in the scope of a modal operator which resides inside the variable's defining fixpoint formula. Intuitively, the effect of this condition is that, when evaluating a guarded formula in some model, between any two iterations of the same fixpoint variable, one has make a transition in the model. Many constructions and algorithms operating on  $\mu$ -calculus formulas presuppose that the input formula is in guarded form, which explains the need for low-cost *guarded transformations*, that is, efficient procedures for bringing a  $\mu$ -calculus formula into an equivalent guarded form.

It is easy to translate the notion of guardedness to parity formulas, but in fact we will need something stronger in the next chapter, when we present the automata-theoretic perspective on the modal  $\mu$ -calculus.

**Definition 6.62** A path  $\pi = v_0 v_1 \cdots v_n$  through a parity formula is *unguarded* if  $n \geq 1$ ,  $v_0, v_n \in \mathsf{Dom}(\Omega)$  while there is no *i*, with  $0 < i \leq n$ , such that  $v_i$  is a modal node. A parity formula is *guarded* if it has no unguarded cycles, and *strongly guarded* if it has no unguarded paths.

In words, a parity formula is strongly guarded if every path, leading from one state (node in  $Dom(\Omega)$ ) to another contains at least one modal node (occurring after the path's starting state). The following theorem states that on arbitrary parity formulas, we can give an exponential-size guarded transformation; note that the index of the formula does not change. At the time of writing it is not known whether every parity formula can be transformed into a guarded equivalent of *subexponential size*.

**Theorem 6.63** There is an algorithm that transforms a parity formula  $\mathbb{G} = (V, E, L, \Omega, v_I)$ into a strongly guarded parity formula  $\mathbb{G}^g$  such that

1)  $\mathbb{G}^{g} \equiv \mathbb{G};$ 2)  $|\mathbb{G}^{g}| \leq 2^{1+|\mathsf{Dom}(\Omega)|} \cdot |\mathbb{G}|;$ 3)  $ind(\mathbb{G}^{g}) \leq ind(\mathbb{G});$ 

We will prove Theorem 6.63 via a construction that step by step improves the 'degree of guardedness' of the parity formula. In the intermediate steps we will be dealing with a modified notion of guardedness.

**Definition 6.64** A parity formula  $\mathbb{G} = (V, E, L, \Omega, v_I)$  is strongly k-guarded if it every unguarded path  $\pi = v_0 v_1 \cdots v_n$  satisfies  $\Omega(v_n) > k$ .

Clearly, a parity formula is (strongly) guarded iff it is (strongly) *m*-guarded, where *m* is the maximum priority value of the formula. Hence, we may prove Theorem 6.63 by successively applying the following proposition. Recall that a parity formula is called *lean* if its priority map is injective. We say that a parity formula has *silent states only* if each of its states is labelled  $\varepsilon$ .

Lectures on the modal  $\mu$ -calculus

**Proposition 6.65** Let  $\mathbb{G}$  be a lean, strongly k-guarded parity formula with silent states only. Then we can effectively obtain a lean, k+1-guarded parity formula  $\mathbb{G}'$ , with silent states only, and such that  $\mathbb{G}' \equiv \mathbb{G}$ ,  $|\mathbb{G}'| \leq 2 \cdot |\mathbb{G}|$  and  $ind(\mathbb{G}') \leq ind(\mathbb{G})$ .

**Proof.** Let  $\mathbb{G} = (V, E, L, \Omega, v_I)$  be an arbitrary lean, strongly k-guarded parity formula with silent states, that is,  $\mathsf{Dom}(\Omega) \subseteq L^{-1}(\varepsilon)$ . Without loss of generality we may assume that in fact  $\mathsf{Dom}(\Omega) = L^{-1}(\varepsilon)$ . If  $\mathbb{G}$  happens to be already k + 1-guarded, then there is nothing to do: we may simply define  $\mathbb{G}' := \mathbb{G}$ .

On the other hand, if  $\mathbb{G}$  is k+1-unguarded, then in particular there must be a state  $z \in V$  such that  $\Omega(z) = k + 1$ . By injectivity of  $\Omega$ , z is unique with this property. In this case we will build the parity formula  $\mathbb{G}'$ , roughly, on the disjoint union of  $\mathbb{G}$ , a copy of a part of  $\mathbb{G}$  that is in some sense generated from z, and an additional copy of z itself.

For the definition of  $\mathbb{G}'$ , let  $W^z$  be the smallest set  $W \subseteq V$  containing z, which is such that  $E[w] \subseteq W$  whenever  $w \in W$  is boolean. Now define

$$V' := (V \times \{0\}) \cup (W^{z} \times \{1\}) \cup (\{z\} \times \{2\}).$$

In the sequel we may write  $u_0$  instead of (u, 0), for brevity. Furthermore, recall that we use  $V_m$  to denote the set of *modal* vertices of  $\mathbb{G}$ . The edge relation E' is now given as follows:

$$E' := \{ (u_0, v_0) \mid (u, v) \in E \text{ and } v \neq z \} \cup \{ (u_1, v_1) \mid (u, v) \in E \text{ and } v \neq z \} \\ \cup \{ (u_0, z_1) \mid (u, z) \in E \} \\ \cup \{ (u_1, v_0) \mid (u, v) \in E \text{ and } u \in V_m \} \cup \{ (u_1, u_0) \mid u \in \mathsf{Dom}(\Omega) \text{ and } \Omega(u) > k+1 \} \\ \cup \{ (u_1, z_2) \mid (u, z) \in E \text{ and } u \notin V_m \}$$

To understand the graph (V', E'), it helps, first of all, to realise that the set  $W^z$  provides a subgraph of (V, E), which forms a dag with root z and such that every 'leaf' is either a modal or propositional node, or else a state  $v \in \mathsf{Dom}(\Omega)$  with  $\Omega(v) > k$ . (It cannot be the case that  $\Omega(v) \leq k$  due to the assumed k-guardedness of  $\mathbb{G}$ .) Second, it is important to realise that the only way to move from the V-part of V' to the  $W^z$ -part is via the root  $z_1$  of the  $W^z$ -part, while the only way to move in the converse direction is either directly following a modal node, or else by making a dummy transition from some vertex  $u_1$  to its counterpart  $u_0$  for any  $u \in W^z$  with  $\Omega(u) > k$ . Finally, we add a single vertex  $z_2$  to V'.

Furthermore, we define the labelling L' and the priority map  $\Omega'$  of  $\mathbb{G}'$  by putting

$$L'(u_i) := \begin{cases} L(u) & \text{if } i = 0, 1\\ \widehat{z} & \text{if } u_i = z_2 \end{cases}$$

where we recall that  $\hat{z} = \bot$  if  $\Omega(z)$  is odd and  $\hat{z} = \top$  if  $\Omega(z)$  is even, and

$$\Omega'(u_i) := \begin{cases} \Omega(u) & \text{if } i = 0 \text{ and } u \in \mathsf{Dom}(\Omega) \\ \uparrow & \text{otherwise.} \end{cases}$$

In words, the label of a node (v, i) in  $\mathbb{G}'$  is identical to the one of v in  $\mathbb{G}$ , with the sole exception of the vertex (z, 2). To explain the label of the latter node, note that by construction, any unguarded E'-path from  $z_1$  to  $z_2$  projects to an unguarded k+1-cycle from

z to z in  $\mathbb{G}$ . If  $\Omega(z) = k + 1$  is odd, any such cycle represents (tails of) infinite matches that are lost by  $\exists$ ; for this reason we may label the 'second' appearance of z in the E'-path, i.e., as the node  $z_2$ , with  $\perp$ .

We now turn to the proof of the proposition. It is not hard to show that  $\mathbb{G}'$  is lean and that  $|\mathbb{G}'| \leq 2 \cdot |\mathbb{G}|$ .

To show that  $ind(\mathbb{G}') \leq ind(\mathbb{G})$ , note that obviously, the projection map  $u_i \mapsto u$  preserves the cluster equivalence relation, i.e.,  $u_i \equiv_{E'} v_j$  implies  $u \equiv_E v$ . Hence, the image of any cluster C' of  $\mathbb{G}'$  under this projection is part of some cluster C of  $\mathbb{G}$ . But then by definition of  $\Omega'$  it is easy to see that  $ind(C') \leq ind(C)$ . From this it is immediate that  $ind(\mathbb{G}') \leq ind(\mathbb{G})$ .

To see why  $\mathbb{G}'$  is k + 1-guarded, suppose for contradiction that it has a k + 1-unguarded path  $\pi = (v_0, i_0)(v_1, i_1) \cdots (v_n, i_n)$ . It is easy to see that this implies that the projection  $v_0v_1 \cdots v_n$  of  $\pi$  is an unguarded path in  $\mathbb{G}$  (here we ignore possible dummy transitions of the form  $(u_1, u_0)$ ), and so by assumption on  $\mathbb{G}$  it must be the case that  $\Omega'(v_n, i_n) = \Omega(v_n) = k+1$ . This means that  $(v_n, i_n) = (z, 0)$ ; but the only way to arrive at the node (z, 0) in (V', E') is directly following a modal node (in  $W^z \times \{1\}$ ), which contradicts the unguardedness of the path  $\pi$ .

In order to finish the proof of the Proposition, we need to prove the equivalence of  $\mathbb{G}'$  and  $\mathbb{G}$ ; but this can be established by a relatively routine argument of which we skip the details. QED

**Proof of Theorem 6.63.** Let  $\mathbb{G}$  be an arbitrary parity formula; without loss of generality we may assume that  $\mathbb{G}$  is lean, i.e.,  $\Omega$  is injective. Let  $\mathsf{Ran}(\Omega) = \{k_1, \ldots, k_n\}$ ; then  $|\mathsf{Dom}(\Omega)| = n$ . To ensure that all states are silent, we may have to duplicate some vertices; that is, we continue with a version  $\mathbb{H}$  of  $\mathbb{G}$  that has at most twice as many vertices, but the same index, the same number of states, and silent state only.

By a straightforward induction we apply Proposition 6.65 to construct, for every  $i \in [1, n]$ , a  $k_i$ -guarded parity automaton  $\mathbb{H}^i$  with silent states only, and such that  $\mathbb{H}^i \equiv \mathbb{G}$ ,  $|\mathbb{H}^i| \leq 2^{i+1} \cdot |\mathbb{G}|$ , and  $ind(\mathbb{H}^i) = ind(\mathbb{G})$ . Clearly then we find that  $\mathbb{H}^n$  is the desired strongly guarded equivalent of  $\mathbb{G}$ ; and since  $n = |\mathsf{Dom}(\Omega)|$  we find that  $|\mathbb{H}^n| \leq 2^{1+n} \cdot |\mathbb{G}|$  as required. QED

**Remark 6.66** On a closer inspection of the construction in the proof of Proposition 6.65, the reader may observe that inductively, we may assume that for every *i*, every predecessor of a state in  $\mathbb{H}^i$  with priority at most  $k_i$  is in fact a modal node. From this, it follows that we may impose, in the formulation of Theorem 6.63, an additional constraint on  $\mathbb{G}^g$ , namely, that every predecessor of a state is a modal node, more formally, that  $(E^g)^{-1}[\mathsf{Dom}(\Omega] \subseteq V_m^g]$ .

# 10 Modal automata

# 10.1 Introduction

In this chapter we introduce and discuss the automata that we shall use to study the modal  $\mu$ -calculus. These automata come in various shapes and types, but they all operate on the same type of structures, namely pointed Kripke structures, or transition systems.

The basic idea is that automata can be seen as alternatives to formulas. In particular, an automaton A will either accept of reject a given pointed Kripke model, and thus it can be compared to a formula  $\xi$ , which will either be true or false at a point in a Kripke model. This inspires the following definition.

**Definition 10.1** Let  $\mathbb{A}$  be an automaton, and assume that we have defined the notions of acceptance and rejection of a pointed Kripke model by such an automaton. In case  $\mathbb{A}$  accepts the pointed Kripke structure  $(\mathbb{S}, s)$  we write  $\mathbb{S}, s \Vdash \mathbb{A}$ , while rejection of  $(\mathbb{S}, s)$  by  $\mathbb{A}$  is denoted as  $\mathbb{S}, s \not\models \mathbb{A}$ . The class of pointed Kripke models that are accepted by a given automaton  $\mathbb{A}$  is denoted as  $\mathcal{Q}(\mathbb{A})$ , and we will sometimes refer to  $\mathcal{Q}(\mathbb{A})$  as the class or query that is recognized by  $\mathbb{A}$ . Two automata  $\mathbb{A}$  and  $\mathbb{A}'$  are equivalent, notation:  $\mathbb{A} \equiv \mathbb{A}'$ , if  $\mathcal{Q}(\mathbb{A}) = \mathcal{Q}(\mathbb{A}')$ .

We say that a formula  $\xi$  is *equivalent* to  $\mathbb{A}$ , notation:  $\xi \equiv \mathbb{A}$ , if  $\mathbb{S}, s \Vdash \xi$  iff  $\mathbb{A}$  accepts  $(\mathbb{S}, s)$ , for every pointed Kripke model  $(\mathbb{S}, s)$ .

All our automata will be of the form  $\mathbb{A} = \langle A, \Theta, Acc, a_I \rangle$  where A is a finite set of states,  $Acc \subseteq A^{\omega}$  is the acceptance condition (usually given by a parity map  $\Omega$ ),  $a_I \in A$  is the starting state of the automaton, and the transition map  $\Theta$  has as its domain the set  $A \times C$ , where  $C = \wp(\mathsf{P})$  is the set of *colors* over some set  $\mathsf{P}$  of proposition letters. We will almost exclusively work with automata that are themselves *logic-based*, in the sense that the co-domain of  $\Theta$ is some logical language consisting of relatively simple *one-step* formulas over the carrier set A of the automata. In other words, the states in A will play a double role as propositional *variables*.

For each type of automaton that we will encounter, the question whether such a device accepts or rejects a given pointed Kripke model  $(\mathbb{S}, s)$  is determined by playing some kind of infinite board game that we call the *acceptance game* associated with the automaton and the Kripke structure. This game will always proceed in *rounds*, each of which starts and ends at a so-called *basic position*  $(a, s) \in A \times S$ , and consists of the two players,  $\exists$  and  $\forall$ , moving a token via some intermediate position(s) to a new basic position. For a rough, intuitive understanding of the acceptance game, the reader may think of  $\exists$  claiming, at a basic position (a, s), that the automaton  $\mathbb{A}$ , taken from the perspective a, is a good 'description' of the pointed structure  $(\mathbb{S}, s)$ .

The rules of the game are determined by the precise shape of the transition function  $\Theta$ , and in each case will be given explicitly. The winning conditions of the acceptance game are fixed. Finite matches, as always, are lost by the player who got stuck. The winner of an infinite match  $\Sigma$  is always determined by applying the acceptance condition Acc to the infinite A-stream  $a_I a_1 a_2 \cdots$  which is induced by the sequence  $(a_I, s)(a_1, s_1)(a_2, s_2) \cdots$  of basic positions occurring in  $\Sigma$ . The definition of acceptance is also fixed: the automaton  $\mathbb{A}$  accepts the pointed Kripke model ( $\mathbb{S}, s$ ) precisely if the pair  $(a_I, s)$  is a winning position for  $\exists$  in the acceptance game.

To understand the connections between the various kinds of automata, it is good to understand how one round of the game takes a match from one basic position  $(a_i, s_i)$  to the next  $(a_{i+1}, s_{i+1})$ . In principle, it is  $\exists$ 's task to propose a set  $Z_i \subseteq A \times S$  of witnesses that substantiate her claim that the automaton  $\mathbb{A}$ , taken from the perspective  $a_i$ , is a good description of the pointed model  $(\mathbb{S}, s_i)$ . Then it is  $\forall$  who picks the new basic position  $(a_{i+1}, s_{i+1})$  as an element of the set  $Z_i$ . In fact, all acceptance games featuring in this chapter could be formulated in such a way that these are exactly the moves that players can make. However, we will usually take a slightly different perspective on the witness relation. In particular, since we are often thinking of A as a set of propositional variables, it will make sense to represent a relation  $Z \subseteq A \times S$  as either a valuation  $V_Z : A \to \wp S$  or as a marking or coloring  $m_Z : S \to \wp A$ , defined by putting, respectively,

$$V_Z(a) := \{ s \in S \mid (a, s) \in Z \} \\ m_Z(s) := \{ a \in A \mid (a, s) \in Z \}.$$

As already mentioned, the automata that we shall meet here come in various shapes, and they can be classified in many ways. One crucial distinction to make is that between *alternating* and *non-deterministic* automata. Where the generic modal automaton that we will introduce here is of the alternating type, many results on the modal  $\mu$ -calculus are proved using the subclass of non-deterministic automata, where the transition map is of a conceptually simpler kind. What makes an automaton *nondeterministic* is the interaction pattern between the two players in the acceptance game: when the automaton is non-deterministic, a winning strategy for  $\exists$  should in principle (but depending on the branching structure of the transition system) reduce the role of  $\forall$  to that of a *path finder* in the model.

▶ For the time being we restrict attention to the mono-modal case.

## 10.2 Modal automata

Modal automata are based on the *modal one-step language*. This language consists of very simple modal formulas, built up from a collection A of propositional *variables*, corresponding to the bound variables of a formula.

**Definition 10.2** Given a set X, we define the set Latt(X) of *lattice terms* over X through the following grammar:

$$\pi ::= \bot \mid \top \mid x \mid \pi \land \pi \mid \pi \lor \pi,$$

where  $x \in X$ . Given a set A, we define the set 1ML(A) of modal one-step formulas over A by the following grammar:

$$\alpha ::= \bot \mid \top \mid \Diamond \pi \mid \Box \pi \mid \alpha \land \alpha \mid \alpha \lor \alpha,$$

with  $\pi \in \text{Latt}(A)$ .

Examples of one-step formula are  $\Diamond(a \land b)$  or  $\Box \bot \lor (\Diamond a \land \Box b)$ . Observe that the set of modal one-step formulas over A corresponds to the set of lattice terms over the set  $\{\Diamond \pi, \Box \pi \mid \pi \in \texttt{Latt}(A)\}$ . Observe too that every occurrence of an element of A must be positive, and in the scope of exactly one modality.

**Definition 10.3** A modal P-automaton  $\mathbb{A}$  is a quadruple  $(A, \Theta, \Omega, a_I)$  where A is a nonempty finite set of states, of which  $a_I \in A$  is the *initial* state,  $\Omega : A \to \omega$  is the *priority map*, and the *transition map* 

$$\Theta: A \times \wp \mathsf{P} \to \mathsf{1ML}(A)$$

maps states to one-step formulas. The class of modal automata over the set P is denoted as  $Aut_{P}(1ML)$ .

The operational semantics of modal automata is defined in terms of a so-called *acceptance* game  $\mathcal{A}(\mathbb{A}, \mathbb{S})$  associated with a modal automaton  $\mathbb{A}$  and a Kripke structure  $\mathbb{S}$ .  $\exists$ 's moves in this game will consist of 'local' valuations for the propositional variables in A, or rather, markings  $m : S \to \wp A$ . Such a marking turns a Kripke model over  $\mathsf{P}$  into a Kripke model over the set  $\mathsf{P} \cup A$ .

Throughout this chapter we will represent a Kripke model (S, R, V) coalgebraically as a triple  $(S, R, \sigma_V)$  where we think of the binary relation R as a map  $R : S \to \wp(S)$ , and represent the valuation  $V : \mathsf{P} \to \wp(S)$  as its transpose colouring  $\sigma_V : S \to \wp(\mathsf{P})$ .

**Definition 10.4** Let P and A be disjoint sets of proposition letters and propositional variables, respectively. Given a Kripke model  $S = (S, R, \sigma_V)$  over the set P, and an A-marking  $m: S \to \wp A$ , we let  $S \oplus m$  denote the Kripke model  $(S, R, \sigma_V \oplus m)$ , where  $\sigma_V \oplus m$  is the marking given by  $\sigma_V \oplus m(s) := \sigma_V(s) \cup m(s)$ .

**Definition 10.5** The acceptance game  $\mathcal{A}(\mathbb{A}, \mathbb{S})$  associated with such an automaton  $\mathbb{A}$  and a pointed Kripke model  $(\mathbb{S}, s)$  is the parity game that is determined by the rules given in Table 19. Positions of the form  $(a, s) \in A \times S$  are called *basic*.

Position	Player	Admissible moves	Priority
$(a,s) \in A \times S$	Э	$\{m: S \to \wp A \mid \mathbb{S} \oplus m, s \Vdash \Theta(a, \sigma_V(s))\}$	$\Omega(a)$
$m: S \to \wp A$	A	$\{(b,t) \mid b \in m(t)\}$	0

Table 19: Acceptance game for modal automata

As explained in the introduction to this chapter, matches of the acceptance game proceed in *rounds*, moving from one basic position to the next. During a round of the game, the players are inspecting a local 'window' into the Kripke model, by means of a one-step formula. Concretely, at the start of a round,  $\exists$ 's task at a basic position (a, s) is to *satisfy* the onestep formula  $\Theta(a, \sigma_V(s))$  at the state s in S. For this purpose, she has to come up with a interpretation for the variables in A, since this is not provided by the valuation V of S. More specifically,  $\exists$  has to select a marking  $m : S \to \wp A$ , in such a way that the formula  $\Theta(a, \sigma_V(s))$  becomes true at s in the model  $\mathbb{S} \oplus m$  (as given in Definition 10.4). Once  $\exists$  has made her choice, it is  $\forall$ 's turn; he needs to pick a new basic position from the witness set  $\{(b,t) \mid b \in m(t)\}$ .

Observe that both players could get stuck in such a match. For instance, it might be impossible for  $\exists$  to satisfy the formula  $\Theta(a, \sigma_V(s))$  at the state *s*, because the formula requires *s* to have successors where it has none. Alternatively, if  $\exists$  could pick the *empty* marking *m* at a position (a, s), then she would immediately win the match since  $\forall$  would get stuck.

#### ▶ examples of modal automata

**Remark 10.6** Note that it is in  $\exists$ 's interest to keep, at any basic position (s, a) of the acceptance game, the set of witnesses as small as possible. More precisely, if at some position (a, s) of the game,  $\exists$  has two admissible markings, say, m and m', at her disposal, and these are such that  $Z_m := \{(b,t) \in S \times A \mid b \in m(t)\} \subseteq Z_{m'} := \{(b,t) \in S \times A \mid b \in m'(t)\}$ , then it will always be to her advantage to choose the marking m rather than m'. In particular, since all occurrences of propositional variables from A in one-step formulas must be in the scope of exactly one modality, to satisfy such a formula at a given point s of the model, the only points that matter are the successors of s. For these reasons, we may without loss of generality restrict the admissible moves of  $\exists$  at a position (a, s) of the acceptance game to those markings m of which the domain is the collection of successors of current point s. In section 10.4 we will work out this perspective.

**Convention 10.7** We will usually identify a match  $\Sigma = (a_0, s_0)m_0(a_1, s_1)m_1(a_2, s_2)m_2...$  of the acceptance game  $\mathcal{A}(\mathbb{A}, \mathbb{S})$  with the sequence  $(a_0, s_0)(a_1, s_1)(a_2, s_2)...$  of its basic positions.

Some basic concepts concerning modal automata are introduced in the following definition.

**Definition 10.8** Fix a modal P-automaton  $\mathbb{A} = (A, \Theta, \Omega, a_I)$ .

Given a state a of  $\mathbb{A}$ , we write  $\eta_a = \mu$  if  $\Omega(a)$  is odd, and  $\eta_a = \nu$  if  $\Omega(a)$  is even; we call  $\eta_a$  the *(fixpoint) type* of a and say that a is an  $\eta_a$ -state. The sets of  $\mu$ - and  $\nu$ -states are denoted with  $A^{\mu}$  and  $A^{\nu}$ , respectively.

The occurrence graph of  $\mathbb{A}$  is the directed graph  $(A, E_{\mathbb{A}})$ , where  $E_{\mathbb{A}}ab$  if b occurs in  $\Theta(a, c)$ for some  $c \in \wp(\mathsf{P})$ . We let  $\triangleleft_{\mathbb{A}}$  denote the transitive closure of the converse relation  $E_{\mathbb{A}}^{-1}$  of  $E_{\mathbb{A}}$  and say that b is active in a if  $b \triangleleft_{\mathbb{A}} a$ . We write  $a \bowtie_{\mathbb{A}} b$  if  $a \triangleleft_{\mathbb{A}} b$  and  $b \triangleleft_{\mathbb{A}} a$ . A cluster of  $\mathbb{A}$  is a cell of the equivalence relation generated by  $\bowtie_{\mathbb{A}}$  (i.e., the smallest equivalence relation on A containing  $\bowtie_{\mathbb{A}}$ ); a cluster C is degenerate if it is of the form  $C = \{a\}$  with  $a \not\bowtie_{\mathbb{A}} a$ . The unique cluster to which a state  $a \in A$  belongs is denoted as  $C_a$ . We write  $a \sqsubset_{\mathbb{A}} b$  if  $\Omega(a) < \Omega(b)$ , and  $a \sqsubseteq_{\mathbb{A}} b$  if  $\Omega(a) \leq \Omega(b)$ .

An alternating  $\Omega$ -chain of length k in  $\mathbb{A}$  is a sequence  $a_0a_1 \cdots a_k$  of states that all belong to the same cluster and satisfy, for all i < k, that  $\Omega(a_i) < \Omega(a_{i+1})$  while  $a_i$  and  $a_{i+1}$  have different parity.

The following proposition is immediate by the definitions.

**Proposition 10.9** Let  $\mathbb{A} = \langle A, \Theta, \Omega, a_I \rangle$  and  $\mathbb{A}' = \langle A, \Theta', \Omega, a_I \rangle$  be two modal automata such that  $\Theta(a, c) \equiv \Theta'(a, c)$  for each  $a \in A$  and  $c \in \wp(\mathsf{P})$ . Then  $\mathbb{A} \equiv \mathbb{A}'$ .

**Remark 10.10** Another way of defining the semantics of modal automata is via the 'slow' acceptance game of Table 20, which is perhaps closer to the evaluation games of the modal  $\mu$ -calculus. In this set-up, at a basic position  $(a, s) \exists$  does not have to come up with a marking m, but rather, the state a is 'unfolded' into the formula  $\Theta(a, \sigma_V(s))$ , and the two players engage in a little sub-game in order to determine whether  $\Theta(a, \sigma_V(s))$  is true at s or not. At the end of this sub-game, unless one of the players got stuck, the match arrives at another basic position. We leave it as an exercise for the reader to check that the two games are in fact equivalent.

Position	Player	Admissible moves	Priority
$(a,s) \in A \times S$	—	$\{(\Theta(a,\sigma_V(s)),s)\}$	$\Omega(a)$
$(\top, s)$	$\forall$	Ø	0
$(\perp, s)$	Е	Ø	0
$(\Diamond \pi, s)$	Э	$\{(\pi,t) \mid t \in R(s)\}$	0
$(\Box \pi, s)$	$\forall$	$\{(\pi,t) \mid t \in R(s)\}$	0
$(\varphi_0 \lor \varphi_1, s)$	Э	$\{(\varphi_0, s), (\varphi_1, s)\}$	0
$(\varphi_0 \land \varphi_1, s)$	$\forall$	$\{(\varphi_0, s), (\varphi_1, s)\}$	0

Table 20: Slow acceptance game for modal automata

Regarding complexity matters, we define the *size* of a modal automaton to get a nice fit with the (slow) acceptance game defined in Remark 10.10. In particular, this means that we cannot simply define the size of an automaton as its number of states, we have to take the *transition map* of the device into account as well. Note that the size  $|\alpha|$  of a modal one-step  $\alpha$  is simply defined as its number of subformulas, or, equivalently, as the size of its closure. The *index* of modal automata is defined in the same way as for parity formulas.

**Definition 10.11** Let  $\mathbb{A} = (A, \Theta, \Omega, a_I)$  be a modal automaton. The *size*  $|\mathbb{A}|$  of  $\mathbb{A}$  is defined as follows:

$$|\mathbb{A}| := \sum_{(a,c)\in A\times C} |\Theta(a,c)|.$$

Its index  $ind(\mathbb{A})$  is given as the maximal length of an alternating  $\Omega$ -chain in  $\mathbb{A}$ .

Later on this chapter we will provide effective translations transforming a  $\mu$ -calculus formula into an equivalent modal automaton, and vice versa. As a corollary of this result we obtain that modal automata are bisimulation invariant — in Exercise 10.2 the reader is asked to give a direct proof.

**Theorem 10.12** Let  $\mathbb{A}$  be a modal automaton. Then for any bisimilar pair  $(\mathbb{S}, s)$  and  $(\mathbb{S}', s')$  of pointed Kripke models it holds that

$$\mathbb{S}, s \Vdash \mathbb{A} \iff \mathbb{S}', s' \Vdash \mathbb{A}.$$

## 10.3 Disjunctive modal automata

A key tool in the study of the model  $\mu$ -calculus is provided by the automata that we are about to introduce now, viz., the nondeterministic variants of the modal automata that we just met in section 10.2. The *disjunctive* automata, as we shall call them, are obtained by restricting the co-domain of the transition map of a modal automaton to the set of so-called disjunctive one-step formulas, which are based on the cover modality discussed in section 1.7.

**Definition 10.13** Given a finite set A, we define the set 1DML(A) of disjunctive modal onestep formulas in A as follows

$$\alpha ::= \bot \mid \top \mid \nabla B \mid \alpha \lor \alpha,$$

where  $B \subseteq A$ .

A modal P-automaton  $\mathbb{A} = (A, \Theta, \Omega, a_I)$  is called *disjunctive* or *non-deterministic* if  $\Theta(a, c) \in 1DML(A)$ , for every  $a \in A$  and  $c \in \wp(\mathsf{P})$ .

▶ example(s) to be supplied

**Remark 10.14** As a variant of Definition 10.13, we will sometimes require that the range of the transition map  $\Theta$  of a disjunctive automaton is given by the formulas of the slightly more restricted one-step language  $1DML_r$  given by the following grammar:

$$\alpha ::= \bot \mid \nabla B \mid \alpha \lor \alpha,$$

where  $B \subseteq A$ . In other words, in this set-up every formula  $\Theta(a, c)$  is a finite disjunction of nabla formulas; the difference with the language of Definition 10.13 is that here, the formula  $\top$  is not allowed.

We leave it as an exercise to the reader to prove that the two versions of the definition are equivalent, in the sense that there are transformations from one type of automaton into the other.  $\triangleleft$ 

As already mentioned, the key property making an automaton *non-deterministic* is that, on Kripke structure with a sufficiently nice branching structure, a winning strategy for  $\exists$  in the acceptance game should always be able to find markings that are *functional*. We will now make this statement more precise.

**Definition 10.15** Let  $\mathbb{A}$  and  $\mathbb{S}$  be a modal automaton and a Kripke structure, respectively. A strategy f for  $\exists$  in the acceptance game  $\mathcal{A}(\mathbb{A}, \mathbb{S})$  is called *separating* if for all partial matches  $\Sigma$  ending in a basic position (a, s), the marking  $m_{\Sigma} : S \to \wp A$  picked by f satisfies  $|m_{\Sigma}(t)| \leq 1$  for all  $t \in S$ , and  $|m_{\Sigma}(t)| = 0$  for all  $t \notin \sigma_R(s)$ .

In words, a strategy is separating if it picks markings that assign to each point in S at most one state in A, and assign the empty set to any point that is not a successor of the currently inspected point of S. For a (non-)example, consider the one-step formula  $\langle a_0 \wedge \Box a_1;$  it should be clear that to satisfy this formula at a point s, one needs at least one successor

of s where both  $a_0$  and  $a_1$  hold. This means that no separating strategy will prescribe a legitimate move for a position of the form (a, s) if the formula that  $\exists$  needs to satisfy is  $\Theta(a, \sigma_V(s)) = \Diamond a_0 \land \Box a_1$ .

Separating winning strategies have the following property, which we will put to good use in the sequel.

**Definition 10.16** Let  $\mathbb{A}$  and  $(\mathbb{S}, r)$  be a modal automaton and a pointed Kripke structure, respectively. A strategy f for  $\exists$  in the acceptance game  $\mathcal{A}(\mathbb{A}, \mathbb{S})@(a_I, r)$  is called *functional* if for every  $s \in S$  there is at most one  $a \in A$  such that the position (a, s) is reachable in an f-guided match of  $\mathcal{A}(\mathbb{A}, \mathbb{S})@(a_I, r)$ .

In case  $\exists$  has a *functional* winning strategy in the acceptance game  $\mathcal{A}(\mathbb{A}, \mathbb{S})@(a_I, r)$ , we say that  $\mathbb{A}$  strongly accepts  $(\mathbb{S}, r)$ , and write  $\mathbb{S}, r \Vdash_s \mathbb{A}$ .  $\triangleleft$ 

**Proposition 10.17** Let  $\mathbb{A}$  be a modal automaton, and let  $(\mathbb{S}, s)$  be a pointed tree model. Then every separating winning strategy in the acceptance game  $\mathcal{A}(\mathbb{A}, \mathbb{S})@(a_I, s)$  is functional.

We have now arrived at the key result about disjunctive automata.

**Theorem 10.18** Let  $\mathbb{A}$  and  $(\mathbb{S}, r)$  be a disjunctive modal automaton and a pointed Kripke model, respectively. Then  $\mathbb{S}, r \Vdash \mathbb{A}$  iff there is a rooted tree model  $(\mathbb{S}', r')$  such that  $\mathbb{S}, r \cong (\mathbb{S}', r')$  and  $\mathbb{S}', r' \Vdash_s \mathbb{A}$ .

**Proof of Theorem 10.18.** With  $\mathbb{A} = (A, \Theta, \Omega, a_I)$ , let  $\kappa := |A|$  be the state-size of  $\mathbb{A}$ . We leave it for the reader to construct a tree model  $\mathbb{S}'$  with root r', and a bounded morphism  $g : \mathbb{S}' \to \mathbb{S}$  such that g(r') = r and such that every  $s' \neq r'$  in  $\mathbb{S}'$  has at least  $\kappa - 1$  many siblings t' such that g(t') = g(s').

By positional determinacy we may assume that  $\exists$  has a positional strategy f in  $\mathcal{A}(\mathbb{A}, \mathbb{S})$  which is winning when played from any winning position for  $\exists$ . We will use this strategy to define a separating positional winning strategy for  $\exists$  in  $\mathcal{A}(\mathbb{A}, \mathbb{S}')$ .

The key claim is the following.

CLAIM 1 Let  $s \in S$  and  $s' \in S'$  be such that g(s') = s, let  $\alpha \in 1DML(A)$  be a one-step formula and let  $m : R(s) \to \wp(A)$  be a marking such that  $\mathbb{S} \oplus m, g(s') \Vdash \alpha$ . Then there is a separating marking  $m' : R'(s') \to \wp(A)$  such that  $\mathbb{S}' \oplus m', s' \Vdash \alpha$  and  $m'(t') \subseteq m(g(t'))$ , for all  $t' \in R'(s')$ .

PROOF OF CLAIM In case  $\alpha$  contains  $\top$  as one of its disjuncts, we simply take the empty marking for m', that is, we define  $m'(t') := \emptyset$  for every  $t' \in S'$ .

In the sequel we focus on the case where  $\alpha$  does not contain  $\top$  as one of its disjuncts (in fact this is without loss of generality, cf. Remark 10.14). It follows from the legitimacy of m, as a move for  $\exists$  in  $\mathcal{A}(\mathbb{A}, \mathbb{S})$ , that  $\mathbb{S}, m, s \Vdash \alpha$ ; this means that  $\mathbb{S} \oplus m, s \Vdash \nabla B$  for some disjunct  $\nabla B$  of  $\alpha$ , where  $B \subseteq A$ . We now consider two subcases.

If  $B = \emptyset$ , it follows from  $\mathbb{S} \oplus m, s \Vdash \nabla B$  that  $\sigma_R = \emptyset$ ; but then we also have  $\sigma_{R'}(s') = \emptyset$ , since g is a bounded morphism. In this case we also define m' as the empty marking.

Finally, assume that  $B \neq \emptyset$ ; since  $\mathbb{S} \oplus m, s \Vdash \nabla B$  we may without loss of generality assume that  $\emptyset \neq m(t) \subseteq B$ , for all  $t \in \sigma_R(s)$ . Now consider an arbitrary successor t of s. By

the assumption on g there are at least  $\kappa$  many successors t' of s' such that g(t') = t, and since  $\kappa = |A|$  this implies that there is a surjection  $h : g^{-1}(t) \to m(t)$ . Define  $m' : \sigma_{R'}(s') \to \wp A$  by putting

$$m'(t') := \{h(t')\}$$

We leave it as an exercise for the reader to check that  $\mathbb{S}', m', s' \Vdash \nabla B$ . This means that  $\mathbb{S}', m', s' \Vdash \alpha$ , thus establishing that m' is a legitimate move for  $\exists$  at position (a, s') in  $\mathcal{A}(\mathbb{A}, \mathbb{S}')$  indeed. Finally, it is immediate from the definition of m' that  $m'(t') \subseteq m(g(t'))$ , for all  $t' \in \sigma_{R'}(s')$ .

Based on Claim 1, we may provide  $\exists$  with the following positional strategy f' in  $\mathcal{A}(\mathbb{A}, \mathbb{S}')$ . Given a position (a, s'), in case (a, g(s')) is a winning position for  $\exists$  in  $\mathcal{A}(\mathbb{A}, \mathbb{S})$ , we let f' pick a fixed marking m' as given by the claim, while f' picks an random move in case  $(a, g(s')) \notin \text{Win}_{\exists}(\mathcal{A}(\mathbb{A}, \mathbb{S}))$ .

It is not hard to prove that for any f'-guided (partial) match  $\Sigma = (a_n, s'_n)_{n < \lambda}$  of  $\mathcal{A}(\mathbb{A}, \mathbb{S}')$ , its g-projection  $\Sigma^g := (a_n, g(s'_n))_{n < \lambda}$  is a f-guided (partial) match of  $\mathcal{A}(\mathbb{A}, \mathbb{S}')$ . From this it is immediate that f' is a winning strategy when played from a winning position, while it is obvious from its definition that f is separating. QED

Further on in this chapter we will prove a *Simulation Theorem*, providing a construction which effectively transforms a given modal automaton into an equivalent disjunctive modal automaton.

## 10.4 One-step logics and their automata

#### Modal one-step logic

As we saw in section 10.2, modal one-step formulas provide the co-domain of the transition map of a modal automaton. The operational semantics of modal automata is given by a two-player acceptance game, and a match of this game proceeds in rounds, during which the players investigate a local window into the Kripke structure, by means of the semantics of one of these one-step formulas. It will be rewarding to introduce some terminology for this 'local window' and study the semantics of one-step formulas in some more detail. This will allow us to introduce the notion of a *one-step logic* and use it to generalise the notion of a modal automaton.

The crucial observation is the following. Consider a modal automaton  $\mathbb{A} = (A, \Theta, \Omega, a_I)$ and a Kripke model S. At a basic position (a, s) of the acceptance game  $\mathcal{A}(\mathbb{A}, \mathbb{S})$ ,  $\exists$  has to come up with a marking m which makes the one-step formula  $\Theta(a, \sigma_V)$  true at s in the expanded model  $\mathbb{S} \oplus m$ . The point is that, because of the special shape of modal one-step formulas, we do not use all information on the model  $\mathbb{S} \oplus m$ : in fact all we need access to is the set R[s] of successors of s, and the marking m. In the sequel it will convenient to present this information in the format of a *one-step model*, which is nothing but a set, together with a marking for the set of variables.

**Definition 10.19** Fix a set A. A one-step A-model over a set Y is a pair (Y, m) such that  $m: Y \to \wp(A)$  is an A-marking of the elements of Y with A-colors.

**Remark 10.20** In order to deal with blind worlds (points in a Kripke model that have no successors), we need to allow one-step models with an *empty domain*. Observe that there is in fact exactly one such structure: the pair  $(\emptyset, \emptyset)$ . Apart from this exception, a one-step model is nothing but a *structure* in the sense of first-order model theory, for the signature consisting of a monadic predicate for each element of A. That is, we may consider the A-model (Y, m) as the structure  $(Y, V_m)$ , simply by representing the marking m by its associated valuation  $V_m$  interpreting the variables as subsets of the domain Y.

**Definition 10.21** The one-step satisfaction relation  $\Vdash^1$  between one-step models and modal one-step formulas is defined as follows. Fix a one-step model (Y, m).

First, we define the value  $[\![\pi]\!]^0$  of a formula  $\pi \in Latt(A)$  by the following induction:

Sometimes we write  $(Y, m), t \Vdash^0 \pi$  in case  $t \in [\![\pi]\!]^0$ .

Second, we inductively define the one-step satisfaction relation as follows:

$$\begin{array}{l} (Y,m) \Vdash^{1} \top \\ (Y,m) \nVdash^{1} \bot \\ (Y,m) \Vdash^{1} \Box \pi & \text{if} \quad \llbracket \pi \rrbracket^{0} = Y \\ (Y,m) \Vdash^{1} \Diamond \pi & \text{if} \quad \llbracket \pi \rrbracket^{0} \cap Y \neq \varnothing \\ (Y,m) \Vdash^{1} \alpha_{0} \land \alpha_{1} & \text{if} \quad (Y,m) \Vdash^{1} \alpha_{0} \text{ and } (Y,m) \Vdash^{1} \alpha_{1} \\ (Y,m) \Vdash^{1} \alpha_{0} \lor \alpha_{1} & \text{if} \quad (Y,m) \Vdash^{1} \alpha_{0} \text{ or } (Y,m) \Vdash^{1} \alpha_{1} \end{array}$$

In case  $(Y, m) \Vdash^1 \alpha$  we say that  $\alpha$  is *true* in the one-step model (Y, m).

**Example 10.22** In this format, the semantics of disjunctive formulas boils down to the following, as can easily be verified, for a subset  $B \subseteq A$ :

$$(Y,m) \Vdash^1 \nabla B$$
 iff  $B \subseteq \bigcup \{m(y) \mid y \in Y\}$  and  $m(y) \cap B \neq \emptyset$ , for all  $y \in Y$ .

That is,  $\nabla B$  holds in a one-step model (Y, m) iff every  $b \in B$  is satisfied at some  $y \in Y$ , and every  $y \in Y$  satisfies some  $b \in B$ .

Furthermore, observe that the empty model will satisfy every formula of the form  $\Box \pi$ , and no formula of the form  $\Diamond \pi$ . We have  $(Y,m) \Vdash^1 \nabla \varnothing$  iff  $Y = \varnothing$ .

The following proposition, which can be proved by a straightforward induction on the complexity of one-step formulas, shows that the one-step semantics developed above is just an alternative perspective on the standard semantics of one-step formulas.

**Proposition 10.23** Let  $\mathbb{S} = (S, R, V)$  be a Kripke model, let s be a point in S, let  $m : R[s] \rightarrow \wp(A)$  be an A-marking, and let  $\alpha \in 1ML(A)$  be a modal one-step formula. Then

$$\mathbb{S} \oplus m, s \Vdash \alpha \text{ iff } (R[s], m) \Vdash^{1} \alpha.$$

Given Proposition 10.23, the acceptance game of modal automata can now be naturally defined in terms of this one-step semantics, as in Table 21.

 $\triangleleft$ 

Position	Player	Admissible moves	Priority
$(a,s) \in A \times S$	Э	$\{m: R(s) \to \wp A \mid (R(s), m) \Vdash^1 \Theta(a, \sigma_V(s))\}$	$\Omega(a)$
m	$\forall$	$\{(b,t) \mid b \in m(t)\}$	0

Table 21: Acceptance game for one-step automata

# General one-step logic

As we will see below, the notion of a one-step logic provides a way to generalise the concept of a modal automaton to a much wider setting.

**Definition 10.24** A one-step language is a map L which assigns to any finite set A a collection L(A) of one-step formulas over A. This map is subject to the constraint that every map  $\tau: A \to A'$  induces a substitution or renaming  $[\tau]: L(A) \to L(A')$  such that 1)  $[id_A] = id_{L(A)};$ 2)  $[\tau' \circ \tau] = [\tau'] \circ [\tau]$ , for any pair  $\tau: A \to A'$  and  $\tau': A' \to A'';$ 3)  $\alpha[\tau] = \alpha$  for any  $\alpha \in L(A)$ , if  $\tau: A \to A'$  is such that  $\tau(a) = a$  for all  $a \in A$ .

We will use postfix notation for this renaming, writing  $\alpha[\tau]$  for the formula we obtain from  $\alpha$  by renaming every variable  $a \in A$  by  $\tau(a) \in A'$ . For instance, where  $\alpha \in 1ML(A)$  is the formula  $\Diamond a \land \Box(b \lor c)$  and  $\tau : A \to A'$  satisfies  $\tau(a) = \tau(c) = a'$  and  $\tau(b) = b'$ , we find  $\alpha[\tau] = \Diamond a' \land \Box(b' \lor a')$ . Note that it follows from the above definition that  $A \subseteq A'$  implies  $L(A) \subseteq L(A')$ , for any one-step language L.

**Definition 10.25** A one-step logic is a pair  $(L, \Vdash^1)$  consisting of a one-step language L and an interpretation  $\Vdash^1$  which indicates, for every one-step A-model (Y, m) and every one-step formula  $\alpha \in L(A)$ , whether  $\alpha$  is true or false in (Y, m), denoted as, respectively,  $(Y, m) \Vdash^1 \alpha$ and  $(Y, m) \not\Vdash^1 \alpha$ .

The interpretation  $\Vdash^1$  is subject to the condition of *monotonicity*: if  $m(t) \subseteq m'(t)$ , for all  $t \in Y$ , then  $(Y,m) \Vdash^1 \alpha$  implies  $(Y,m') \Vdash^1 \alpha$ , for all  $\alpha \in L(A)$ . Furthermore, the interpretation is supposed to be well-behaved with respect to renamings, in the following sense. Observe that a map  $\tau : A' \to A$  transforms any A-valuation  $V : A \to \wp(Y)$  to an A'-valuation  $V \circ \tau : A' \to \wp(Y)$ ; we will require that  $(Y,m_V) \Vdash^1 \alpha[\tau]$  iff  $(Y,m_{V\circ\tau}) \Vdash^1 \alpha$ , for any formula  $\alpha \in L(A)$ .

We will generally be sloppy and blur the distinction between a one-step language and a one-step logic, in the understanding that the interpretation of one-step languages is generally fixed (and always clear from context).

In Definition 10.21 we introduced the one-step perspective on modal logic. As a different, particularly interesting example of a one-step logic, we may consider two versions of *monadic* first-order logic, where we see the variables in A as monadic predicate symbols.

**Definition 10.26** The set MFOE(A) of monadic first-order formulas over A is given by the following grammar:

 $\alpha ::= \top \mid \perp \mid a(x) \mid \neg a(x) \mid x \doteq y \mid x \neq y \mid \alpha \lor \alpha \mid \alpha \land \alpha \mid \exists x.\alpha \mid \forall x.\alpha$ 

where  $a \in A$  and x, y are first-order (individual) variables. The language MFO(A) of monadic first-order logic is the equality-free fragment of MFOE(A); that is, atomic formulas of the form  $x \doteq y$  and  $x \neq y$  are not permitted:

$$\alpha ::= \top \mid \perp \mid a(x) \mid \neg a(x) \mid \alpha \lor \alpha \mid \alpha \land \alpha \mid \exists x.\alpha \mid \forall x.\alpha$$

In both languages we use the standard definition of free and bound variables, and we call a formula a *sentence* if it has no free variables. For each of the languages  $L \in \{1F0, 1F0E\}$ , we define the *positive fragment*  $L^+$  of L as the language obtained by almost the same grammar as for L, but with the difference that we do not allow negative formulas of the form  $\neg a(x)$ (but do allow formulas  $x \neq y$ ).

To define the *semantics* of these formulas, we make a distinction between the empty onestep model and non-empty models, cf. Remark 10.20. In the latter case we view a one-step model (Y, m) as the first-order structure  $(Y, V_m)$ . If we add to such a model an *assignment* g, interpreting individual variables of the language as elements of the domain, we may inductively define, in a completely straightforward way, the notion of a monadic formulas being *true* in a model-with-assignment:

$$(Y,m),g\models\alpha.$$

Note the truth of a *sentence* of the language does not depend on the assignment, so that may simply write

$$(Y,m) \models \alpha$$

in case  $(Y, m), g \models \alpha$  for some/each assignment.

The *empty* model must be dealt with differently. Since we cannot define assignments on the empty model in a meaningful way, we cannot interpret arbitrary formulas in the empty model. Fortunately, however, we can give an interpretation for every *sentence* of the language, simply by making every formula of the form  $\forall x.\alpha \ true$ , and every formula of the form  $\exists x.\alpha \ false$  in the empty model. Using this as a basis for an inductive definition, we easily define a truth relation

$$(\emptyset, \emptyset) \models \alpha$$

for any monadic first-order sentence  $\alpha$ .

In the light of the above discussion, we will take the (positive) sentences of the languages MFOE(A) and MFOE(A) as two respective one-step languages.

**Definition 10.27** We define the one-step languages 1FOE(A) and 1FO(A) as the collection of positive sentences in MFOE(A) and MFOE(A), respectively. The semantics  $\Vdash^1$  of these languages is defined by putting

$$(Y,m) \Vdash^1 \alpha \text{ iff } (Y,m) \models \alpha,$$

for any one-step model (Y, m).

## **One-step** logic

Continuing our general discussion, we introduce some natural notions pertaining to one-step logics.

**Definition 10.28** Two one-step formulas  $\alpha$  and  $\alpha'$  are *(one-step) equivalent*, denoted  $\alpha \equiv_1 \alpha'$ , if they are satisfied by exactly the same one-step models.

**Example 10.29** Examples of one-step equivalent pairs of formulas include instance of the standard propositional distributive laws, such as the modal distributive law:

$$(\diamondsuit a_1 \lor \diamondsuit a_2) \land \Box b \equiv_1 (\diamondsuit a_1 \land \Box b) \lor (\diamondsuit a_2 \land \Box b),$$

the familiar axioms of modal logic, such as

$$\Box(a \wedge b) \equiv_1 \Box a \wedge \Box b,$$

but also formulas involving the nabla modality, such as

$$\nabla B \wedge \nabla B' \equiv_1 \bigvee \left\{ \nabla \{ b \wedge b' \mid bRb' \} \mid R \subseteq B \times B' \text{ and } (B, B') \in \overline{\wp}R \right\}$$

(cf. Proposition 1.36(1)).

Examples such as

$$\Diamond (a_1 \wedge a_2) \wedge \Box b \equiv_1 \exists x \, (a_1(x) \wedge a_2(x)) \wedge \forall y \, b(y).$$

show that Definition 10.28 also covers the notion of one-step equivalence across languages.  $\triangleleft$ 

We may lift the notion of equivalence to the level of one-step logics.

**Definition 10.30** We say that two one-step  $(L, \Vdash^1)$  and  $(L', \Vdash^1')$  languages are *(effectively)* equivalent if for every formula in L there is an (effectively obtainable) equivalent formula in L', and vice versa.

A particular interesting example of such an equivalence is the following.

## Proposition 10.31 The one-step languages 1ML and 1FO are effectively equivalent.

**Proof.** It is easy to rewrite a modal one-step formula into an equivalent first-order formula. For the opposite direction, the key observation is that in equality-free *monadic* first-order logic, every formula can be rewritten into a normal form where every monadic predicate is in the scope of exactly one quantifier. QED

Among the results about the modal one-step language that we shall need later is the following one-step version of the usual bisimulation invariance result for modal logic, i.e. all one-step formulas are invariant for bisimulations between one-step models in a precise sense.

Lectures on the modal  $\mu$ -calculus

**Definition 10.32** We say that two one-step A-models (Y, m) and (Y', m') are one-step bisimilar, notation:  $(Y, m) \Leftrightarrow^1 (Y', m')$ , if they satisfy the following conditions:

(forth) for all  $s \in S$ , there is  $s' \in S'$  with m(s) = m'(s');

(back) for all  $s' \in S'$ , there is  $s \in S$  with m(s) = m'(s').

**Proposition 10.33 (One-step Bisimulation Invariance)** Let (Y, m) and (Y', m') be two one-step A-models. If  $(Y, m) \leq^1 (Y', m')$ , then both one-step models satisfy the same formulas in 1ML(A).

#### Automata for one-step logics

We now see how the concept of one-step logic naturally give rise to the following generalisation of modal automata.

**Definition 10.34** Let  $(L, \Vdash^1)$  be a one-step logic. An L-*automaton* over a set P of proposition letters is a quadruple  $\mathbb{A} = \langle A, \Theta, \Omega, a_I \rangle$ , where A is a finite state set with initial state  $a_I$ ,  $\Theta : A \times \wp(\mathsf{P}) \to \mathsf{L}(A)$  is a transition function, and  $\Omega : A \to \omega$  is a priority map.

The *semantics* of L-automata is given by a two-player acceptance game, of which the rules are given in exactly the same way as those for modal automata, cf. Table 21.  $\triangleleft$ 

As we will see later on, the automata for 1F0 and 1F0E are of particular interest since they correspond to, respectively, the modal  $\mu$ -calculus and (on tree models) monadic second-order logic. The first observation is immediate by our earlier observations on the equivalence of  $\mu$ ML and modal automata, and Proposition 10.31.

An important theme in the study of these automata is how their properties are already determined at the one-step level. Here are some first examples, regarding the closure properties of L-automata. Recall that a *query* is simply a class of pointed Kripke models.

**Definition 10.35** Given be a one-step logic  $(L, \Vdash^1)$ , we call a query K L-*recognisable* if there is some L-automaton A that *recognises* K, i.e., such that  $S, s \Vdash A$  iff S, s belongs to K.

We will generally be interested in *closure properties* of the class of recognisable queries. It is rather easy to see that if a one-step language is closed under taking conjunctions/disjunctions, then the associated class of recognisable languages is closed under taking intersections/unions. The question of closure under complementation is more interesting; note that since our one-step languages consist of *monotone* formulas only, closure under negation at the one-step level is not possible.

**Definition 10.36** Let  $(L, \Vdash^1)$  be a one-step logic. We say that L is closed under taking conjunctions, if, given a pair of one-step formulas  $\alpha$  and  $\beta$ , there is a one-step formula  $\gamma$  such that any one-step model satisfies  $\gamma$  iff it satisfies both  $\alpha$  and  $\beta$ . The notion of closure under disjunctions is defined analogously.

Given two one-step formulas  $\alpha$  and  $\beta$  in L(A), we call  $\beta$  a *boolean dual* of  $\alpha$  if for every one-step model (Y, m) we have that

$$(Y,m) \Vdash^1 \beta$$
 iff  $(Y,\overline{m}) \not\Vdash^1 \alpha$ ,

where  $\overline{m}$  is the complement marking of m, given by  $\overline{m}(t) := A \setminus m(t)$ , for all  $t \in Y$ . We say that L is closed under taking boolean duals if every formula in L has a boolean dual in L.

**Example 10.37** The one-step modal language is closed under taking conjunctions, disjunctions and boolean duals. We let  $\alpha^{\partial}$  be the formula we obtain from a formula  $\alpha \in 1ML$  by simultaneously replacing all occurrences of  $\perp$  by  $\top$ , all conjunctions by disjunctions, all diamonds by boxes, and vice versa. For example:  $(\Diamond \top \land \Box(a \lor b))^{\partial} = \Box \bot \lor \Diamond(a \land b)$ . It is easy to verify that for every  $\alpha \in 1ML$ , the formulas  $\alpha$  and  $\alpha^{\partial}$  are boolean duals of one another.

The one-step language of *disjunctive* modal logic is closed under taking disjunctions, but not conjunctions or boolean duals.  $\triangleleft$ 

## **Proposition 10.38** Let $(L, \Vdash^1)$ be a one-step logic.

- 1) If L is closed under taking conjunctions, then the L-recognisable queries are closed under taking intersections.
- 2) If L is closed under taking disjunctions, then the L-recognisable queries are closed under taking unions.
- 3) If L is closed under taking boolean duals, then the L-recognisable queries are closed under complementation.

**Proof.** We leave the proof of the first two statements as an exercise to the reader. For the proof of the third part we need to show that with any L-automaton  $\mathbb{A}$  we can associate an L-automaton  $\overline{\mathbb{A}}$  which accepts exactly those pointed Kripke models that are rejected by  $\mathbb{A}$ .

Let  $\mathbb{A} = (A, \Theta, \Omega, a_I)$  be an L-automaton, and define  $\overline{\mathbb{A}}$  to be the structure  $\overline{\mathbb{A}} := (A, \Theta^{\partial}, \Omega', a_I)$ given by putting  $\Theta^{\partial}(a, c) := \Theta(a, c)^{\partial}$  and  $\Omega'(a) := 1 + \Omega(a)$ .

Now take an arbitrary pointed Kripke model  $(\mathbb{S}, s)$ . Comparing the acceptance games  $\mathcal{A}(\mathbb{A}, \mathbb{S})$  and  $\mathcal{A}(\overline{\mathbb{A}}, \mathbb{S})$  we observe that the role of  $\exists$  in the latter game is basically the same as that of  $\forall$  in the first. From this it follows that any position (a, s) is winning for  $\exists$  in  $\mathcal{A}(\overline{\mathbb{A}}, \mathbb{S})$  iff it is winning for  $\forall$  in  $\mathcal{A}(\mathbb{A}, \mathbb{S})$ . Using determinacy we derive that  $\mathbb{S}, s \Vdash \overline{\mathbb{A}}$  iff  $\mathbb{S}, s \not\Vdash \mathbb{A}$ , as required. QED

## 10.5 From formulas to automata and back

In this section we will substantiate our earlier claim that modal automata are indeed an alternative way to look at the modal  $\mu$ -calculus. That is, we will provide effective constructions that transform a (parity) formula into an equivalent modal automaton, and vice versa. In both directions we will let these transformations pass via the intermediate structures of *transparent modal automata*; these are variations of modal automata in which the proposition letters, instead of featuring as part of the domain of the transition map, may occur on the co-domain side. That is, we have to extend the definition of one-step formulas, allowing (unguarded) occurrences of proposition letters.

**Definition 10.39** Given a set P of proposition letters and a set A of propositional variables, we define the set  $1\text{EML}(\mathsf{P}, A)$  of *extended* one-step modal formulas over P and A using the following grammar:

 $\alpha ::= \bot \mid \top \mid p \mid \overline{p} \mid \Diamond \pi \mid \Box \pi \mid \alpha \land \alpha \mid \alpha \lor \alpha,$ 

with  $P \in \mathsf{P}$  and  $\pi \in \mathsf{Latt}(A)$ .

Observe that in an extended modal one-step formula, the proposition letters from P may only occur 'at the surface', that is, *not* in the scope of a modality; as in 1ML(A)-formulas, every occurrence of a variable from A must be in the scope of exactly one modality.

**Definition 10.40** A transparent modal automaton over a set P of proposition letters is a quadruple of the form  $\mathbb{A} = (A, \Theta, \Omega, a_I)$ , where A is a finite set of states, of which  $a_I$  is the *initial* state,  $\Omega : A \to \omega$  is a priority map, and

$$\Theta: A \to \mathtt{1EML}(\mathsf{P}, A)$$

is the transition map.

Given a Kripke model  $\mathbb{S} = (S, R, V)$ , we define the *acceptance game*  $\mathcal{A}(\mathbb{A}, \mathbb{S})$  as the parity game of which the admissible moves and the priority map are given in Table 22.

Position	Player	Admissible moves	Priority
$(a,s) \in A \times S$	_	$\{(\Theta(a),s)\}$	$\Omega(a)$
$(p,s)$ , with $p \in P$ and $s \in V(p)$	A	Ø	0
$(p,s)$ , with $p \in P$ and $s \notin V(p)$	Э	Ø	0
$(\overline{p}, s)$ , with $p \in P$ and $s \in V(p)$	Э	Ø	0
$(\overline{p}, s)$ , with $p \in P$ and $s \notin V(p)$	A	Ø	0
$(\top, s)$	A	Ø	0
$(\perp, s)$	E	Ø	0
$(\varphi_0 \lor \varphi_1, s)$	Е	$\{(\varphi_0,s),(\varphi_1,s)\}$	0
$(\varphi_0 \land \varphi_1, s)$	A	$\{(\varphi_0, s), (\varphi_1, s)\}$	0
$(\Diamond \pi, s)$	Э	$\{(\pi,t) \mid t \in R(s)\}$	0
$(\Box \pi, s)$	$\forall$	$\{(\pi,t) \mid t \in R(s)\}$	0

Table 22: Acceptance game for transparent modal automata

The key feature of this acceptance game is that at a basic position of the form  $(a, s) \in A \times S$ , the one-step formula  $\Theta(a)$  that  $\exists$  needs to satisfy at s does not depend on the colour of s. On the other hand, this formula may now contain literals over P, and in this way the colour of s does play a role when the players evaluate the truth of  $\Theta(a)$ .

In the sequel we will refer to standard modal automata (i.e., as given in Definition 10.3) as *chromatic* to distinguish them from the transparent ones introduced here.

The main part of this section consists of constructions that transform chromatic modal automata into transparent ones and vice versa, and transform parity formulas into transparent modal automata and vice versa. In all cases we will compare the *size* and *index* of the input and the output structure (these notions are defined for transparent automata as for chromatic ones). Throughout the remainder we fix a set P of proposition letters, and we think of the sizes of P and  $\wp(P)$  as being constant.

**Proposition 10.41** There is an effective construction that transforms a transparent modal P-automaton  $\mathbb{A}$  into a chromatic modal P-automaton  $\mathbb{A}^c$ , such that

1)  $\mathbb{A}^{c} \equiv \mathbb{A};$ 2)  $|\mathbb{A}^{c}| = \mathcal{O}(|\mathbb{A}|);$ 3)  $ind(\mathbb{A}^{c}) = ind(\mathbb{A}).$ 

**Proof.** The intuition behind the transformation is that in the acceptance game for a transparent automaton we may encounter literals over P, which are to be evaluated at the current state. Depending on the colour of the current state, every such literal will be evaluated to be either true or false. This means, that if we fix this colour, as we do in the acceptance game of a chromatic automaton, we can simply *replace* every literal with the appropriate boolean constant ( $\top$  or  $\perp$ ), thus obtaining at a one-step formula in the 'not-extended' language 1ML(A). Performing this substitution systematically, we arrive at the following definitions.

Given a colour  $c \in \wp(\mathsf{P})$ , we define the substitution  $\tau_c : 1\mathsf{EML}(\mathsf{P}, A) \to 1\mathsf{ML}(A)$  given by

$$\tau_c(p) := \begin{cases} \top & \text{if } p \in c \\ \bot & \text{if } p \notin c. \end{cases}$$

Based on this we go from a transparent modal automaton  $\mathbb{A} = (A, \Theta, \Omega, a_I)$  to its chromatic counterpart  $\mathbb{A}^c := (A, \Theta', \Omega, a_I)$  by putting

$$\Theta'(a,c) := \Theta(a)[\tau_c].$$

The key observation about these substitutions is that for any Kripke model S = (S, R, V)over P, any s in S, any A-marking m on s, and any extended one-step formula  $\alpha$  we have

$$\mathbb{S} \oplus m, s \Vdash \alpha \text{ iff } \mathbb{S} \oplus m, s \Vdash \alpha[\tau_{c_s}],$$

where  $c_s$  is the colour of s under V.

It is this equivalence that enables us to move smoothly between the acceptance games  $\mathcal{A}(\mathbb{A}, \mathbb{S})$  and  $\mathcal{A}(\mathbb{A}^c, \mathbb{S})$ : it shows that at any basic position (a, s), any marking  $m : S \to \wp(A)$  is legitimate in  $\mathcal{A}(\mathbb{A}, \mathbb{S})$  iff it is legitimate in  $\mathcal{A}(\mathbb{A}^c, \mathbb{S})$ . From this we easily infer that the winning positions for  $\exists$  in the two games coincide, which clearly suffices to prove the equivalence of  $\mathbb{A}$  and  $\mathbb{A}^c$  (1). The statements (2) and (3) are trivial consequences of the definitions. QED

In the opposite direction there is an equally simple transformation.

**Proposition 10.42** There is an effective construction that transforms a chromatic modal P-automaton  $\mathbb{A}$  into a transparent modal P-automaton  $\mathbb{A}^t$ , such that

1)  $\mathbb{A}^t \equiv \mathbb{A};$ 2)  $|\mathbb{A}^t| = \mathcal{O}(|\mathbb{A}|);$ 3)  $ind(\mathbb{A}^t) = ind(\mathbb{A}).$ 

**Proof.** Let  $\mathbb{A} = (A, \Theta, \Omega, a_I)$  be a chromatic automaton over some set  $\mathsf{P}$  of proposition letters. We will define  $\mathbb{A}^t := (A, \Theta^t, \Omega, a_I)$ , where  $\Theta^t : A \to \texttt{1EML}(\mathsf{P}, A)$  is given by

$$\Theta^t(a) := \bigvee_{c \in \wp(\mathsf{P})} \Big( \odot c \land \Theta(a, c) \Big).$$

Lectures on the modal  $\mu$ -calculus

Here  $\odot c$  is the formula 'exactly c':

$$\bigcirc c := \bigwedge_{p \in c} p \land \bigwedge_{p \in \mathsf{P} \backslash c} \overline{p},$$

which holds in a state s in a Kripke model over  $\mathsf{P}$  if c is exactly the colour of s. It is easily verified that  $\mathbb{A}^t$  satisfies the conditions listed in the statement of the theorem. QED

We now turn to the equivalence of parity formulas and transparent modal automata. The transformation of the first into the latter type of structure is the most complex construction in this section — but the hardest part of the work has already been done in section 6.6 where we discussed *guarded transformations* of parity formulas.

**Proposition 10.43** There is an effective construction that transforms a parity P-formula  $\mathbb{G}$  into a transparent modal P-automaton  $\mathbb{A}_{\mathbb{G}}$ , such that

1) 
$$\mathbb{A}_{\mathbb{G}} \equiv \mathbb{G};$$
  
2)  $|\mathbb{A}_{\mathbb{G}}| \leq 2^{\mathcal{O}(|\mathbb{G}|)}$   
3)  $ind(\mathbb{A}_{\mathbb{G}}) = ind(\mathbb{G}).$ 

**Proof.** Recall that by Theorem 6.63 there is an algorithm that transforms  $\mathbb{G}$  into an equivalent strongly guarded parity formula  $\mathbb{H}$  of size (roughly) exponential in  $|\mathbb{G}|$ , and index  $ind(\mathbb{H}) = ind(\mathbb{G})$ . Without loss of generality we may assume that every state of  $\mathbb{H}$  is the successor of some modal node, cf. Remark 6.66.

The transparent modal automaton  $\mathbb{A}$  will be directly based on  $\mathbb{H}$ . First of all, we let the carrier A of  $\mathbb{A}$  be the set of successors of modal nodes, together with the initial vertex  $v_I$ , that is:

$$A := \{v_I\} \cup E[V_m].$$

Clearly then all states of  $\mathbb{H}$  belong to A, and with every modal node u we may associate an element  $a_u \in A$ : its unique successor. We define  $a_I := v_I$ , and as the priority map of  $\mathbb{A}$  we take the map  $\Omega' : A \to \omega$  given by

$$\Omega'(a) := \begin{cases} \Omega(a) & \text{if } a \in \mathsf{Dom}(\Omega) \\ 0. & \text{otherwise} \end{cases}$$

It is left to define the transition map  $\Theta : A \to 1\text{EML}(\mathsf{P}, A)$ . Basically, for any  $a \in A$  we will read off  $\Theta(a)$  from a directed acyclic graph  $\mathbb{D}_a := (D_a, E_a)$  that we will cut out from the underlying graph (V, E) of  $\mathbb{H}$ . We define  $D_a$  as the smallest subset D of V that contains a and is closed under taking E-successors of non-modal nodes (that is, if  $v \in D \setminus V_n$ , then  $E[v] \subseteq D$ ). Clearly, any node  $u \in D_a$  must be either modal or atomic if E[u] is empty, and either boolean or silent if it is not. The relation  $E_a$  can now be defined as follows:

$$E_a := \{ (u, v) \in E \cap (D_a \times D_a) \mid v \neq a \}.$$

It follows from the strong guardedness of  $\mathbb{H}$  that  $\mathbb{D}$  is *acyclic*, so that we may use the relation  $E_a$  for recursive definitions. (It is for this reason that we did not define  $E_a$  as the *restriction* 

of E to the set  $D_a$ ; this would create cycles in case  $D_a$  would contain a modal node u such that Eua.) In particular, we will define a formula  $\theta_a(u) \in 1$ EML for every  $u \in D_a$ :

$$\theta_a(u) := \begin{cases} L(u) & \text{if } u \text{ is atomic} \\ \heartsuit a_u & \text{if } u \text{ is modal and } L(u) = \heartsuit \\ \bigcirc \{L(v) \mid Euv\} & \text{if } u \text{ is boolean and } L(u) = \odot \\ \theta_a(v) & \text{if } L(u) = \varepsilon \text{ and } Euv. \end{cases}$$

Finally, then, we define

$$\Theta(a) := \theta_a(a).$$

It is easy to verify that every formula of the form  $\theta_a(u)$  is an extended modal one-step formula over P and A. This implies that  $\Theta: A \to 1\text{EML}(\mathsf{P}, A)$  is of the required type.

It is an immediate consequence of the definitions that  $|\mathbb{A}| \leq \mathbb{H}$  and  $ind(\mathbb{A}) \leq ind(\mathbb{H})$ ; from this we obtain the items (2) and (3) of the theorem. It thus remains to prove the equivalence of  $\mathbb{A}$  and  $\mathbb{H}$ . But a moment of reflection will show that, for any Kripke model  $\mathbb{S}$ , the evaluation game  $\mathcal{E} := \mathcal{E}(\mathbb{H}, \mathbb{S})$  and the acceptance game  $\mathcal{A} := (\mathbb{A}, \mathbb{S})$  are *isomorphic*, apart from the automatic moves of type  $(a, s) \to (\Theta(a), s)$  in  $\mathcal{A}$ , which have no counterpart in  $\mathcal{E}$ . QED

**Proposition 10.44** There is an effective construction that transforms a transparent modal P-automaton A into a parity P-formula  $\mathbb{G}_A$ , such that

1)  $\mathbb{G}_{\mathbb{A}} \equiv \mathbb{A};$ 2)  $|\mathbb{G}_{\mathbb{A}}| = |\mathbb{A}|;$ 3)  $ind(\mathbb{G}_{\mathbb{A}}) = ind(\mathbb{A}).$ 

**Proof.** Given  $\mathbb{A} = (A, \Theta, \Omega, a_I)$ , define  $\mathbb{G}_{\mathbb{A}} = (V, E, L, \Omega, v_I)$  by putting

$$V := A \cup \bigcup_{a \in A} Sf(\Theta(a))$$
  

$$E := \{(a, \Theta(a)) \mid a \in A\} \cup (\triangleright_0 \cap (V \times V))$$
  

$$\Omega(v) := \begin{cases} \Omega(v) & \text{if } v \in A \\ \uparrow & \text{otherwise} \end{cases}$$
  

$$v_I := a_I,$$

where we recall that  $\triangleright_0$  is the converse of the direct subformula relation  $\triangleleft_0$ . We leave it for the reader to verify that  $\mathbb{G}_{\mathbb{A}}$  satisfies the conditions (1), (2) and (3). QED

## 10.6 Simulation Theorem

In this section we will prove the most important result of this chapter, viz., the *Simulation Theorem* stating that every modal automaton can be replaced with an equivalent disjunctive modal automaton.

**Theorem 10.45** There is a construction sim transforming a modal automaton  $\mathbb{A}$  into an equivalent disjunctive modal automaton sim( $\mathbb{A}$ ).

The definition of the simulating automaton proceeds in two stages. We first come up with an automaton  $\mathbb{A}^{\sharp}$  of which the transition map already has the right shape, but the acceptance condition is not a parity condition but a so-called  $\omega$ -regular set over the carrier  $A^{\sharp}$  of  $\mathbb{A}^{\sharp}$  (i.e., a subset of  $(A^{\sharp})^{\omega}$  that itself can be recognized by some finite stream automaton with a parity acceptance condition). As we shall see, the move from  $\mathbb{A}$  to  $\mathbb{A}^{\sharp}$  involves a 'change of basis': the states of  $\mathbb{A}^{\sharp}$  will be taken from the set  $A^{\sharp} := \wp(A \times A)$  of binary relations over A, and the definition of the transition map  $\Theta^{\sharp}$  of  $\mathbb{A}^{\sharp}$  is based on various links between the one-step languages we obtain by taking A and  $A^{\sharp}$  as sets of (formal) variables. In the second step of the construction we then show how  $\mathbb{A}^{\sharp}$ , like any automaton with a  $\omega$ -regular acceptance condition, can be transformed into a standard modal automaton with a parity condition.

In fact, we shall prove a slightly more general version of Theorem 10.45, by abstracting from the precise shape of the one-step languages 1ML and 1DML that form the codomain of the transition function of modal and disjunctive modal automata, respectively. Our proof will only use a certain distributive law that holds between 1ML and 1DML, and for future reference it will make sense to formulate our definitions and results for two arbitrary one-step languages satisfying such a distributive law.

**Convention 10.46** Throughout this section we we shall be dealing with two one-step languages  $L_1$  and  $L_2$ , providing sets  $L_i(A)$  of formulas for each set A of propositional variables.

Recall that, in line with the context of fixpoint logics that we are working in, we will assume that, for any one-step logic L, the formulas in L(A) are all *monotone*. Recall as well that in Definition 10.34 we introduced the notion of an L-automaton, and that in Table 21 we summarize the rules of the acceptance game of such automata.

Our purpose will be to prove that, under some natural constraints on the relation between two one-step languages  $L_1$  and  $L_2$ , every  $L_1$ -automaton can be *simulated by* an  $L_2$ -automaton, that is, transformed into an equivalent  $L_2$ -automaton. In the case where  $L_1 = 1ML$  and  $L_2 = 1DML$ , the simulating language 1DML corresponds to some *fragment* of 1ML, in which the use of conjunctions is severely restricted. Here the construction of the simulating automaton corresponds to finding a *disjunctive normal form* for the modal automata.

In order to formulate the condition on  $L_1$  and  $L_2$  under which we can prove a simulation theorem, we need some preparatory work. Informally, let  $L^{\wedge}(A)$  denote the version of the language L that allows conjunctions of proposition letters from A to occur at positions where L only allows the proposition letters from A themselves. As an example, recall that the language 1DML(A) is built up from basic formulas  $\nabla B$ , where  $B \subseteq A$ . Examples of formulas in 1DML<sup> $\wedge$ </sup>(A) are  $\nabla\{a \land b, b\}$  and  $\perp \lor \nabla\{a_1 \land a_2 \land a_3, \top\}$ . Observe that these two formulas do not belong to 1DML(A), and thus bear witness to the fact that the latter language forms a *proper* subset of 1DML<sup> $\wedge$ </sup>(A). On the other hand, it is easy to see that 1ML(A) = 1ML<sup> $\wedge$ </sup>(A).

A convenient way of thinking about the formulas in  $L^{\wedge}(A)$  is that they are *substitution* instances of formulas in  $L(\wp A)$  under a special substitution  $\theta_A$ . Formally we define the language as follows.

**Definition 10.47** For any set A and any language L, we define the language

$$\mathsf{L}^{\wedge}(A) := \{\varphi[\theta_A] \mid \varphi \in \mathsf{L}(\wp A)\},\$$

where we let  $\theta_A$  denote the substitution that replaces, for any subset  $B \subseteq A$ , the (formal) variable B with the conjunction  $\bigwedge B$ .

As an example, we obtain the formula  $\Box a \land \Box (a \land b) \in 1ML(A)$  from the formula  $\Box \{a\} \land \Box \{a, b\} \in 1ML(\mathsf{P}, \wp A)$  by substituting  $a = \bigwedge \{a\}$  for  $\{a\}$ , and  $a \land b = \bigwedge \{a, b\}$  for  $\{a, b\}$ .

Now we can define the key condition on two languages  $L_1$  and  $L_2$ , making that  $L_2$ -automata can simulate  $L_1$ -automata, as follows.

**Definition 10.48** L<sub>2</sub> is  $\bigwedge$ -distributive over L<sub>1</sub> if, for each set A, and for every finite set  $\Phi$  of L<sub>1</sub>(A)-formulas we have

$$\bigwedge \Phi \equiv \psi[\theta_A],$$

for some formula  $\psi \in L_2(\wp A)$ .

Informally,  $L_2$  is  $\bigwedge$ -distributive over  $L_1$  if every finite conjunction of  $L_1(A)$ -formulas is equivalent to some  $L_2^{\wedge}(A)$ -formula. The terminology can be motivated as follows:  $L_2$  is  $\bigwedge$ distributive over  $L_1$  if every conjunction of  $L_1$ -formulas is equivalent to an  $L_2$ -formula of conjunctions; that is, if conjunctions in  $L_1$  'distribute over  $L_2$ -formulas'. As a key example of  $\bigwedge$ -distributivity we have the following result, which can be proved along the same lines as Proposition 1.36.

**Proposition 10.49** 1DML(A) is  $\bigwedge$ -distributive over 1ML(A).

The importance of the notion of  $\wedge$ -distributivity lies in the following Theorem, which obviously generalises the simulation theorem for modal automata.

**Theorem 10.50 (Simulation Theorem)** Let  $L_1$  and  $L_2$  be two one-step languages such that  $L_2$  is  $\wedge$ -distributive over  $L_1$ . Then there is an effective construction sim transforming an  $L_1$ -automaton  $\mathbb{A}$  into an equivalent  $L_2$ -automaton sim( $\mathbb{A}$ ).

We now turn to the definition of the L<sub>2</sub>-automaton  $\mathbb{A}^{\sharp}$  that simulates an arbitrary but fixed L<sub>1</sub>-automaton  $\mathbb{A}$ . Note that our prime example concerns a simulation theorem where the transition structure of the simulating automaton is of a significantly simpler nature than that of the simulated one. The intuition underlying the definition of  $\mathbb{A}^{\sharp}$  is that one  $\mathbb{A}^{\sharp}$ -match will correspond to a *bundle of several*  $\mathbb{A}$ -matches in parallel, and that to win an  $\mathbb{A}^{\sharp}$ -match,  $\exists$ has to win *each* of these parallel  $\mathbb{A}$ -matches. It is thus to be expected that we will obtain  $\mathbb{A}^{\sharp}$ via some kind of power construction on  $\mathbb{A}$ .

For some more detail, suppose that  $\exists$  is faced with a set  $\{(a, s) \mid a \in B_s\}$  of positions in some A-acceptance game, for some subset  $B_s \subseteq A$  (and one single state s). She could try to respond to all challenges posed by these positions *in one go* by coming up with a single marking  $m : R[s] \to \wp A$  such that  $(R[s], m) \Vdash^1 \bigwedge \{\Theta(a, c_s) \mid a \in B\}$ . Then for each such successor t of s, we can see  $B_t = m(t)$  as the set of new challenges that she should take care of at t in parallel. In this way, we may think of a match of the simulating automaton moving in rounds, from one 'macro-position'  $(B_i, s_i)$  (corresponding to the set  $\{(b, s_i) \mid b \in B_i\}$ ) to another 'macro-position'  $(B_{i+1}, s_{i+1})$  (corresponding to the set  $\{(b, s_{i+1}) \mid b \in B_{i+1}\}$ ).

This approach would suggest to take  $\wp A$  as the carrier set of  $\mathbb{A}^{\sharp}$ . However, if we would simply take the states of  $\mathbb{A}^{\sharp}$  to be *macro-states* of  $\mathbb{A}$ , i.e., subsets of  $\mathbb{A}$ , we would get into trouble when defining the acceptance condition of  $\mathbb{A}$ , similar to the problems one encounters when determinizing stream automata. The problem is that from a sequence  $B_1B_2B_3...$  of subsets of A, representing an  $\mathbb{A}^{\sharp}$ -match, we cannot recognize the set of parallel  $\mathbb{A}$ -matches that this sequence corresponds to. We can take an elegant way out of this problem by defining the carrier set  $A^{\sharp}$  of  $\mathbb{A}^{\sharp}$  to be the set of *binary relations* over A, and to link  $A^{\sharp}$ -sequences and A-sequences via the notion of a *trace* through a sequence of binary relations.

**Definition 10.51** Fix a set A. We let  $A^{\sharp}$  denote the set of binary relations over A, that is,

$$A^{\sharp} := \wp(A \times A).$$

Given an infinite word  $\rho = R_1 R_2 R_3 \dots$  over the set  $A^{\sharp}$ , a *trace* through  $\rho$  is either a finite A-word  $\alpha = a_0 a_1 a_2 \dots a_k$ , or an A-stream  $\alpha = a_0 a_1 a_2 \dots$ , such that  $a_i R_{i+1} a_{i+1}$  for all i < k (respectively, for all  $i < \omega$ ). Finite traces through finite  $A^{\sharp}$ -sequences are defined similarly.  $\triangleleft$ 

The key idea behind the definition of  $\mathbb{A}^{\sharp}$  and the proof of its equivalence to  $\mathbb{A}$ , is that with each  $\mathcal{A}(\mathbb{A}^{\sharp}, \mathbb{S})$ -match with basic positions

$$(R_1, s_1)(R_2, s_2)(R_3, s_3)\dots$$

and each trace  $a_0a_1a_2$  through  $R_1R_2R_3...$  we may associate an  $\mathcal{A}(\mathbb{A}, \mathbb{S})$ -match with basic positions

$$(a_1, s_1)(a_2, s_2)(a_3, s_3)\dots$$

This explains the winning condition of the automaton  $\mathbb{A}^{\sharp}$ : an explain  $a_0$  vs  $a_1$   $\mathbb{A}^{\sharp}$ -stream • should be winning for  $\exists$  if *all* traces through it are winning according to the acceptance condition of  $\mathbb{A}$ .

**Definition 10.52** Relative to a parity condition  $\Omega$  on A, call an infinite trace  $\alpha \in A^{\omega}$  bad if the maximum priority occurring infinitely often on  $\alpha$  is an odd number. Let  $NBT_{\Omega}$  denote the set of infinite  $A^{\sharp}$ -words that contain no bad traces relative to  $\Omega$ .

Note that the automaton  $\mathbb{A}^{\sharp}$  will be equipped with this set  $NBT_{\Omega}$  as its acceptance condition, and while we will be able to establish that  $\mathbb{A}^{\sharp}$  is equivalent to  $\mathbb{A}$ ,  $NBT_{\Omega}$  clearly is not a parity condition. This we will take care of in the second part of the construction.

Before giving the formal details, let us first provide some further intuitions behind the definition of  $\mathbb{A}^{\sharp}$ . Our starting point is that a state R of  $\mathbb{A}^{\sharp}$  encodes the macro-state  $\operatorname{Ran}(R) := \{b \in A \mid (a, b) \in R \text{ for some } a \in A\}$ , that is, the range of R. This already suffices to motivate the definition of the initial state of  $\mathbb{A}^{\sharp}$ :

$$R_I := \{(a_I, a_I)\}.$$

In order to introduce the definition of  $\Theta^{\sharp} : (A^{\sharp} \times \wp \mathsf{P}) \to \mathsf{L}_2(A^{\sharp})$ , consider a model S and a position of the form (R, s) in the acceptance game  $\mathcal{G}^{\sharp} = \mathcal{A}(\mathbb{A}^{\sharp}, \mathbb{S})$ . Take a state  $a \in \mathsf{Ran}(R)$ , then at the position (a, s) in the game  $\mathcal{G} = \mathcal{A}(\mathbb{A}, \mathbb{S})$ ,  $\exists$  has to come up with a marking

 $m_{a,s}: R[s] \to \wp(A)$  such that  $(R[s], m_{a,s}) \Vdash^1 \Theta(a, c_s)$ . Since the position (R, s) encodes the 'macro-position'  $\{(a, s) \mid a \in \operatorname{Ran}(R)\}$ , we need to consider all of the formulas  $\Theta(a, c_s)$ (with  $a \in \operatorname{Ran}(R)$ ) in parallel; this would suggest to consider the conjunction  $\bigwedge \{\Theta(a, c_s) \mid a \in \operatorname{Ran}(R)\}$ . However, in this conjunction we are no longer able to retrieve the 'origin' of a propositional variable  $b \in A$ . For this reason we use the following trick. We consider any pair  $(a, b) \in A \times A$  as a new propositional variable, representing the variable b tagged with the 'origin' a.

**Definition 10.53** Given a language L and a variable a, let  $\tau_a$  be the substitution replacing any variable  $b \in A$  with the variable  $(a, b) \in A \times A$ . In words, we say that  $\tau_a$  tags each variable b with a. Given a state a of  $\mathbb{A}$  and a color  $c \in \wp \mathsf{P}$ , let  $\Theta^*(a, c) \in \mathsf{L}_1(A \times A)$  be the formula

$$\Theta^{\star}(a,c) := \Theta(a,c)[\tau_a],$$

that is, each  $b \in A$  occurring in  $\Theta(a)$  is replaced with (a, b).

As an example, if  $\Theta(a,c) = \Diamond a \land \Box b$ , then  $\Theta^{\star}(a,c) = \Diamond(a,a) \land \Box(a,b)$ .

Using this trick we can think of a state  $R \in A^{\sharp}$  unfolding into the formula  $\bigwedge \{\Theta^{\star}(a, c_s) \mid a \in \operatorname{Ran}(R)\} \in L_1(A \times A)$ . Observe that any variable in this formula that is in the scope of a modality, must be of the form  $(a, b) \in A \times A$ , thus encoding a 'direct meaning' b together with its 'origin' a. Also note that any binary relation  $Q \in A^{\sharp}$  now represents a set of (formal) variables, and so it makes sense to consider for instance the conjunction  $\bigwedge Q$ .

The following proposition is immediate by the definitions.

**Proposition 10.54** Let  $L_1$  and  $L_2$  be two languages such that  $L_2$  is  $\bigwedge$ -distributive over  $L_1$ , and let A be some set. Then for every finite set  $\Phi$  of formulas in  $L_1(A \times A)$  there is a formula  $\psi \in L_2(A^{\sharp})$  such that

$$\bigwedge \Phi \equiv \psi[\theta_{A \times A}], \tag{118}$$

where  $\theta_{A \times A}$  is the substitution replacing every relation  $Q \subseteq A \times A$  with the conjunction  $\bigwedge Q$ .

We are now ready for the formal definition of the automaton  $\mathbb{A}^{\sharp}$ .

**Definition 10.55** Let  $L_1$  and  $L_2$  be two languages such that  $L_2$  is  $\bigwedge$ -distributive over  $L_1$ , and let  $\mathbb{A} = \langle A, \Theta, \Omega, a_I \rangle$  be an  $L_1$ -automaton.  $\mathbb{A}^{\sharp}$  is given as the  $L_2$ -automaton

$$\mathbb{A}^{\sharp} := \langle A^{\sharp}, \Theta^{\sharp}, \mathrm{NBT}_{\Omega}, R_I \rangle.$$

Here  $A^{\sharp} = \wp(A \times A)$  is the set of binary relations on A, the initial state  $R_I$  is the relation  $R_I := \{(a_I, a_I)\}$ . The transition function  $\Theta^{\sharp}$  is given by fixing, for  $\Theta^{\sharp}(R, c)$ , a formula  $\psi \in L_2(A^{\sharp})$  satisfying

$$\bigwedge \{ \Theta^{\star}(a,c) \mid a \in \mathsf{Ran}(R) \} \equiv \psi[\theta_{A \times A}], \tag{119}$$

Finally, the acceptance condition  $NBT_{\Omega} \subseteq (A^{\sharp})^{\omega}$  is as given in Definition 10.52.

The main technical result of this section concerns the following equivalence.

 $\triangleleft$ 

Lectures on the modal  $\mu$ -calculus

**Proposition 10.56** Let  $L_1$  and  $L_2$  be two languages such that  $L_2$  is  $\bigwedge$ -distributive over  $L_1$ , and let  $\mathbb{A}$  be an  $L_1$ -automaton. Then  $\mathbb{A}$  is equivalent to  $\mathbb{A}^{\sharp}$ .

A key proposition, relating the various formulas, languages and substitutions that feature in the simulation construction, is the following.

**Proposition 10.57** Let  $\mathbb{A}$  be an  $\mathbb{L}_1$ -automaton and let D be some set. Suppose that for each  $a \in A$  a marking  $m_a : D \to \wp A$  is given. For  $R \in A^{\sharp}$ , let  $m_R : D \to \wp (A \times A)$  and  $m_R^{\sharp} : D \to \wp (A^{\sharp})$  be the markings given by

$$\begin{split} m_R(d) &:= \{(a,b) \mid a \in \mathsf{Ran}(R) \ \& \ b \in m_a(d) \} \\ m_R^{\sharp}(d) &:= \{m_R(d)\}. \end{split}$$

Then the following are equivalent, for any  $c \in \wp \mathsf{P}$ :

- 1.  $(D, m_a) \Vdash^1 \Theta(a, c)$  for each  $a \in \mathsf{Ran}(R)$ ;
- 2.  $(D, m_R) \Vdash^1 \bigwedge \{ \Theta^*(a, c) \mid a \in \mathsf{Ran}(R) \};$
- 3.  $(D, m_R^{\sharp}) \Vdash^1 \Theta^{\sharp}(R, c).$

We leave the (straightforward) proof of this Proposition as an exercise to the reader.

**Proof of Proposition 10.56.** Fix an arbitrary pointed model  $(S, s_0)$ , then it suffices to prove that

$$A \text{ accepts } (\mathbb{S}, s_0) \text{ iff } \mathbb{A}^{\sharp} \text{ accepts } (\mathbb{S}, s_0).$$
 (120)

For the direction from left to right, define a position (R, s) to be *safe* if for all  $a \in \mathsf{Ran}(R)$ , (a, s) is winning for  $\exists$  in the acceptance game  $\mathcal{G} = \mathcal{A}(\mathbb{A}, \mathbb{S})@(a_I, s_0)$ . Now define the following strategy for  $\exists$  in  $\mathcal{G}^{\sharp} = \mathcal{A}(\mathbb{A}^{\sharp}, \mathbb{S})@(R_I, s_0)$ :

- If (R, s) is safe, then  $\exists$  uses Proposition 10.57 to transform the set of moves  $\{m_{a,s} \mid a \in \mathsf{Ran}(R)\}$ , given by her winning strategy in  $\mathcal{G}$ , into a marking  $m_{R,s}^{\sharp} : R[s] \to \wp A^{\sharp}$ .
- If (R, s) is not safe, then  $\exists$  plays in a random way.

It is not very hard to prove the following three claims on this strategy.

CLAIM 1 If (R, s) is safe then the moves suggested by the above strategy are legitimate.

CLAIM 2 If (R, s) is safe then all pairs (Q, t) such that  $Q \in m_{R,s}^{\sharp}(t)$  are safe.

CLAIM 3 Consider an infinite  $\mathcal{G}^{\sharp}$ -match, guided by the above strategy for  $\exists$ , with basic positions  $(R_I, s_0)(R_1, s_1)(R_2, s_2) \dots$ , and let  $a_I a_I a_1 a_2 \dots$  be a trace through  $R_I R_1 R_2 \dots$  Then there is an infinite  $\mathcal{G}$ -match, guided by  $\exists$ 's winning strategy, of which the basic positions are  $(a_I, s_0)(a_1, s_1)(a_2, s_2) \dots$ 

On the basis of these three claims, it easily follows that the given strategy is winning for  $\exists$  from any safe position. In particular, it follows from the assumption that  $(a_I, s_0) \in \text{Win}_{\exists}(\mathcal{G})$  that  $(R_I, s_0)$  is safe, and hence winning for  $\exists$  in  $\mathcal{G}^{\sharp}$ . This shows that  $\mathbb{A}^{\sharp}$  accepts  $(\mathbb{S}, s_0)$ , as required.

The proof of the opposite direction (' $\Leftarrow$ ') of (120) is somewhat similar, and left as an exercise. QED

#### **Regular** automata

In the previous subsection we defined a nondeterministic automaton  $\mathbb{A}^{\sharp}$  and proved it to be equivalent to the given automaton  $\mathbb{A} = \langle A, \Theta, \Omega, a_I \rangle$ . The only shortcoming of the automaton  $\mathbb{A}^{\sharp}$  is that its acceptance condition  $\operatorname{NBT}_{\Omega} \subseteq (A^{\sharp})^{\omega}$  is not given by a parity function. We will now see that this problem can easily be overcome since  $\operatorname{NBT}_{\Omega}$  has the form of an  $\omega$ -regular language over the alphabet  $A^{\sharp}$ , that is, it is recognized by some stream automaton.

**Definition 10.58** An automaton  $\mathbb{A} = \langle A, \Theta, Acc, a_I \rangle$  is called  $\omega$ -regular if  $Acc \subseteq A^{\omega}$  is an  $\omega$ -regular language, i.e., if Acc is the stream language recognized by some deterministic stream automaton with a parity (or Muller) acceptance condition.

Here we shall prove that, given an regular automaton  $\mathbb{A}$  of which the acceptance condition is given by some deterministic parity stream automaton  $\mathbb{Z}$ , we can effectively construct a parity automaton  $\mathbb{A} \odot \mathbb{Z}$  that is equivalent to  $\mathbb{A}$ . First, however, we show that, indeed,  $\mathbb{A}^{\sharp}$  is a regular automaton, by constructing a stream automaton recognizing the  $\omega$ -language NBT<sub> $\Omega$ </sub>.

**Proposition 10.59** Let A be some finite set, and let  $\Omega : A \to \omega$  be a parity function on A. Then the set NBT<sub> $\Omega$ </sub> is an  $\omega$ -regular language over the alphabet  $A^{\sharp}$ .

**Proof.** First we define a nondeterministic  $A^{\sharp}$ -stream parity automaton  $\mathbb{B}$  which accepts exactly those infinite  $A^{\sharp}$ -streams that do contain a bad trace. Given the properties of parity stream automata it is fairly straightforward to continue from here. First, take a deterministic equivalent  $\mathbb{B}'$  of  $\mathbb{B}$ ; such an automaton exists by Theorem 4.27. And second, since  $\mathbb{B}'$  is deterministic, it is easy to perform complementation on it, that is, define an automaton  $\mathbb{C}$  that accepts exactly those  $A^{\sharp}$ -streams that are rejected by  $\mathbb{B}'$ . In short:  $L_{\omega}(\mathbb{C}) = (A^{\sharp})^{\omega} \setminus L_{\omega}(\mathbb{B}') =$  $(A^{\sharp})^{\omega} \setminus L_{\omega}(\mathbb{B})$ . Clearly then  $L_{\omega}(\mathbb{C}) = \operatorname{NBT}_{\Omega}$ .

For the definition of  $\mathbb{B}$ , take an object  $b_I \notin A$ , and define  $B := A \cup \{b_I\}$ . Let  $\Delta : B \times A^{\sharp} \to \wp(B)$  be given by putting

$$\Delta(b,R) := \begin{cases} \mathsf{Ran}(R) & \text{if } b = b_I, \\ R[b] & \text{if } b \in A, \end{cases}$$

and define  $\Omega^{+1}$  by putting  $\Omega^{+1}(a) := \Omega(a) + 1$  for  $a \in A$ , and  $\Omega^{+1}(b_I) := 0$ . Then  $\mathbb{B}$  is the automaton  $\langle B, \Delta, \Omega^{+1}, b_I \rangle$ .

It is immediate from the definitions that  $b_I \xrightarrow{R} a$  iff  $a \in \operatorname{Ran}(R)$ , that is, if there is some  $a' \in A$  such that a'Ra. From this and the definition of  $\Delta$  it follows that

$$b_I \xrightarrow{R_1} a_1 \xrightarrow{R_2} a_2 \xrightarrow{R_3} \dots$$

is a run of  $\mathbb{B}$  iff there is some  $a_0 \in A$  such that  $a_0 a_1 a_2 \dots$  is a trace through  $R_1 R_2 \dots$  Then the definition of  $\Omega^{+1}$  ensures that  $\mathbb{B}$  indeed accepts those  $A^{\sharp}$ -streams that contain a bad trace. QED

It follows from Proposition 10.59 that the automaton  $\mathbb{A}^{\sharp}$  defined in the previous section is a regular automaton. Hence we have proved the main result of this section if we can show that

every disjunctive regular automaton can be replaced by a disjunctive modal automaton with a parity acceptance condition. This is what we will focus on now. In fact, we will effectively transform a nondeterministic, regular automaton  $\mathbb{A}$  (of which the acceptance condition is given as the stream language recognized by some stream automaton  $\mathbb{Z}$ ) into an equivalent parity automaton  $\mathbb{A} \odot \mathbb{Z}$ .

**Definition 10.60** Let  $\mathbb{Z} = \langle Z, \zeta, \Omega, a_I \rangle$  be a deterministic parity A-stream automaton, and let  $\mathbb{A} = \langle A, \Theta, Acc, a_I \rangle$  be a disjunctive modal automaton. Then  $\mathbb{A} \odot \mathbb{Z}$  is the disjunctive modal automaton given as

$$\mathbb{A} \odot \mathbb{Z} = \langle A \times Z, \Theta^{\zeta}, \Psi, (a_I, z_I) \rangle,$$

where  $\Theta^{\zeta} : ((A \times Z) \times \wp \mathsf{P}) \to \mathsf{1DML}(A \times Z)$  is given by

$$\Theta^{\zeta}((a,z),c) := \Theta(a,c)[(b,\zeta(z,a))/b \mid b \in A],$$

and

$$\Psi(a,z) := \Omega(z)$$

defines  $\Psi: A \times Z \to \omega$ .

Intuitively, the automaton  $\mathbb{A} \odot \mathbb{Z}$  behaves like  $\mathbb{A}$ , with the stream automaton  $\mathbb{Z}$  following and directly processing the path through  $\mathbb{A}$  taken during a match of the acceptance game. More precisely, when the automaton  $\mathbb{A}$  moves from state a to b, the corresponding moves of  $\mathbb{A} \odot \mathbb{Z}$  are from any position (a, z) to  $(b, \zeta(z, a))$ , where  $\zeta(z, a)$  is the state obtained from zby processing the 'letter' a. Formally, this is established by the transition structure  $\Theta^{\zeta}$  of the automaton  $\mathbb{A} \odot \mathbb{Z}$  as follows:  $\Theta^{\zeta}((a, z), c)$  is obtained from  $\Theta(a, c)$  by substituting every occurrence of a  $b \in A$  by the ('formal') variable  $(b, \zeta(z, a)) \in A \times Z$ .

**Theorem 10.61** Let  $\mathbb{Z} = \langle Z, \zeta, \Omega, z_I \rangle$  be a deterministic parity stream automaton, and let  $\mathbb{A} = \langle A, \Theta, Acc, a_I \rangle$  be a disjunctive modal automaton such that  $Acc = L_{\omega}(\mathbb{Z})$ . Then  $\mathbb{A}$  and  $\mathbb{A} \odot \mathbb{Z}$  are equivalent.

▶ Proof of Theorem 10.61 to be supplied

Finally, for the proof of the Simulation Theorem we need to combine various results obtained in this Chapter.

**Proof of Theorem 10.50.** It follows from the Propositions 10.49, 10.56 and 10.59 that every modal automaton can be simulated by a disjunctive, regular automaton. Then the Simulation Theorem follows by combining this observation with Theorem 10.61. QED

## 11 Model theory of the modal $\mu$ -calculus

In this Chapter we will see how to apply the automata-theoretic tools developed in the previous chapter to prove some model-theoretic results about the modal  $\mu$ -calculus.

▶ overview of chapter to be supplied

## 11.1 Small model property

As our first result we will prove a small model property for the modal  $\mu$ -calculus, by showing that if a modal automaton accepts some pointed Kripke model, it accepts one of which the size is bounded by the size of the automaton. Recall that, given a modal automaton  $\mathbb{A}$  we refer to the class of pointed Kripke models that are accepted by  $\mathbb{A}$  as the *query* of  $\mathbb{A}$ , notation:  $\mathcal{Q}(\mathbb{A})$ , and that classes of this form are called *recognizable*.

**Theorem 11.1** Let  $\mathbb{A}$  be a modal automaton. Then  $\mathcal{Q}(\mathbb{A}) \neq \emptyset$  iff  $\mathbb{A}$  accepts a finite pointed model of size at most exponential in the state-size of  $\mathbb{A}$ .

Because of the Simulation Theorem it suffices to prove Theorem 11.1 for *disjunctive* modal automata. Our proof will be based on an alternative perspective of these devices, revealing their close resemblance the Kripke models that they operate on.

#### Kripke automata

The key observation in our proof is that the semantics of the cover modality and the notion of a bisimulation are defined in a very similar fashion, both involving the coalgebraic presentation of Kripke models, and the notion of *relation lifting*.

Fix a set P of proposition letters. Recall from Remark 1.3 and Definition 1.4 that we can represent a Kripke model<sup>9</sup> (S, R, V) as a pair

$$\mathbb{S} = (S, \sigma : S \to \mathsf{K}S),$$

where K is the Kripke functor given by putting, for an arbitrary set S:

$$\mathsf{K}S := \wp(\mathsf{P}) \times \wp(S).$$

In Definition 1.29 we introduced two notions of *relation lifting*. Given a binary relation  $Z \subseteq S \times S'$ , we define the relation  $\overline{\wp}Z \subseteq \wp S \times \wp S'$  as follows:

$$\overline{\wp}Z := \{(X, X') \mid \text{ for all } x \in X \text{ there is an } x' \in X' \text{ with } (x, x') \in Z \\ \& \text{ for all } x' \in X' \text{ there is an } x \in X \text{ with } (x, x') \in Z \}.$$

Similarly, define, associated with the Kripke functor K, the relation  $\overline{\mathsf{K}}Z \subseteq \mathsf{K}S \times \mathsf{K}S'$  as follows:

$$\overline{\mathsf{K}}Z := \{ ((\pi, X), (\pi', X')) \mid \pi = \pi' \text{ and } (X, X') \in \overline{\wp}Z \}.$$

<sup>&</sup>lt;sup>9</sup>We restrict to the monomodal case in this section.

Position	Player	Admissible moves
$(a,s) \in A \times S$		$\{(\alpha(a), \sigma(s))\}$
$(\beta,\tau) \in KA \times KS$	Ξ	$\{Z \in \wp(A \times S) \mid (\beta, \tau) \in \overline{K}Z\}$
$Z \in \wp(A \times S)$	$\forall$	$Z = \{(b,t) \mid (b,t) \in Z\}$

Table 23: Bisimilarity game for Kripke models

To make our point we now introduce a new class of automata, consisting of so-called *Kripke automata*, and show that these are in fact equivalent to the disjunctive automata defined earlier on.

As our starting point we consider, for two Kripke models  $\mathbb{A} = \langle A, \alpha \rangle$  and  $\mathbb{S} = \langle S, \sigma \rangle$ , the bisimilarity game  $\mathcal{B}(\mathbb{A}, \mathbb{S})$  of Definition 1.26. Using the above notion of relation lifting, the rules of this game can be reformulated as in Table 23. Recall that the winning conditions of the bisimilarity game are such that all infinite games are won by  $\exists$ .

The main conceptual step is to think of  $\mathbb{A}$  as a 'proto-automaton' that we use to *classify*  $\mathbb{S}$  rather than as of a Kripke model that we are comparing with  $\mathbb{S}$ . In order to turn  $\mathbb{A}$  into a proper Kripke automaton, four technical modifications have to be made:

(1) A small change is that we require  $\mathbb{A}$  (i.e., its carrier set A) to be finite.

(2) Second, and equally undramatic, we add an initial state to the structure of A.

(3) Third, whereas the winner of an infinite match of a bisimulation game is always  $\exists$ , the winner of an infinite acceptance match will be determined by an explicit acceptance condition on  $A^{\omega}$  — a parity condition, in our case.

(4) The fourth and foremost modification is that we introduce *nondeterminism* to the transition structure of  $\mathbb{A}$ . That is, Kripke automata will harbour many 'realizations' of Kripke models — and in each round of the acceptance game, it is  $\exists$ 's task to pick an actual local realization of the current state of  $\mathbb{A}$ .

**Definition 11.2** Given a set P of proposition letters, a *Kripke automaton* for P is a quadruple  $\mathbb{A} = \langle A, \Delta, \Omega, a_I \rangle$  such that the transition function  $\Delta$  is given as a map  $\Delta : A \to \wp(\mathsf{K}A)$ . The *acceptance game*  $\mathcal{A}(\mathbb{A}, \mathbb{S})$  associated with a Kripke automaton  $\mathbb{A} = \langle A, \Delta, \Omega, a_I \rangle$  and a Kripke structure  $\mathbb{S}$  is given by Table 24. A pointed Kripke model  $(\mathbb{S}, s)$  is *accepted* by  $\mathbb{A}$  if the position

Position	Player	Admissible moves	Priority
$(a,s) \in A \times S$		$\{(\gamma, \sigma(s)) \in KA \times KS \mid \gamma \in \Delta(a)\}$	$\Omega(a)$
$(\gamma,\tau)\inK A\timesK S$	Ξ	$\{Z \subseteq A \times S \mid (\gamma, \tau) \in \overline{K}Z\}$	0
$Z\in\wp(A\times S)$	$\forall$		0

Table 24: Acceptance game for Kripke automata

 $(a_I, s)$  is a winning position for  $\exists$  in the acceptance game.

For an informal description of the acceptance game  $\mathcal{A}(\mathbb{A}, \mathbb{S})$ , note that each round consists of exactly three moves, with interaction pattern  $\exists \exists \forall$ . At a basic position (a, s), the 'Kunfolding'  $\sigma(s) \in \mathsf{K}S$  of s is fixed, but  $\exists$  chooses the unfolding of a to be an arbitrary element

 $\gamma$  of  $\Delta(a)$ . After this move, the play arrives at a position of the form  $(\gamma, s) \in \mathsf{K}A \times S$ . The players now proceed as in the bisimilarity game for Kripke models. First  $\exists$  chooses a 'local bisimulation' linking  $\gamma$  and  $\sigma(s)$ , that is, a relation  $Z \subseteq A \times S$  such that  $(\gamma, \sigma(s)) \in \overline{\mathsf{K}}Z$ . Spelled out, this means that  $\exists$  can only choose such a relation Z if  $\gamma$  is of the form  $(c, B) \in \wp(\mathsf{P}) \times \wp(A)$  with  $c = \sigma_V(s)$ , and that Z has to satisfy the back and forth conditions, stating that for all  $b \in B$  there is  $t \in R[s]$  with bZt, and vice versa. The round ends with  $\forall$  choosing an element (b, t) from Z, thus providing the next basic position of the match.

We will now show that Kripke automata are nothing but disjunctive automata in disguise, and vice versa.

**Definition 11.3** First let  $\mathbb{A} = \langle A, \Delta, \Omega, a_I \rangle$  be some Kripke automaton. We define its modal companion  $\mathbb{A}^M$  as the disjunctive modal automaton  $\mathbb{A}^M := \langle A, \Delta^M, \Omega, a_I \rangle$ , where  $\Delta^M : A \times \wp(\mathsf{P}) \to \mathsf{1DML}(A)$  is given by putting

$$\Delta^M(a,c) := \bigvee \{ \nabla B \mid (c,B) \in \Delta(a) \}.$$

Conversely, let  $\mathbb{D} = \langle D, \Theta, \Omega, d_I \rangle$  be a disjunctive modal automaton. Without loss of generality we may assume that the domain of  $\Theta$  consists of formulas in the restricted format of Remark 10.14, that is, for every pair  $(a, c) \in A \times \wp(\mathsf{P})$  there is a (possibly empty) index set  $I_{a,c}$  such that

$$\Theta(a,c) = \bigvee \{ \nabla B_i \mid i \in I_{a,c} \}$$

We now define the transition map  $\Delta_{\Theta}$  by putting

$$\Delta_{\Theta}(a) := \{ (c, B_i) \in \mathsf{K}A \mid c \in \wp(\mathsf{P}), i \in I_{a,c} \},\$$

and define  $\mathbb{D}^K := \langle D, \Delta_{\Theta}, \Omega, d_I \rangle$  and call this structure the *Kripke companion* of  $\mathbb{D}$ .

**Remark 11.4** For a better understanding of the equivalence between disjunctive modal automata and Kripke models, it may be useful to take the following perspective. Given sets P (of proposition letters) and A of states, it is not hard to see that the collection of possible transition functions of disjunctive modal automata (in the restricted format of Remark 10.14 corresponds to the set

$$T_D := (A \times \wp(\mathsf{P})) \to \wp(\wp(A)),$$

while the set of possible transition maps of Kripke automata is given as the collection

$$T_K := A \to \wp(\wp(\mathsf{P}) \times \wp(A)).$$

Now recall that by 'currying' there is a bijective correspondence

 $(\dagger) \ (X \times Y) \to Z \ \cong \ X \to (Y \to Z)$ 

for any triple of sets X, Y and Z. Furthermore, for any set X there is a well-known bijective correspondence between the powerset  $\wp(X)$  of X and the collection of functions from X to the two-element set  $2 := \{0, 1\}$ : (‡)  $\wp(X) \cong X \to 2$ . Using these observations it is straightforward to verify the following bijective correspondences between the sets  $T_D$  and  $T_K$ :

$$\begin{array}{l} \left(A \times \wp(\mathsf{P})\right) \to \wp\wp(A) \\ \cong (\ddagger) \quad \left(A \times \wp(\mathsf{P})\right) \to \left(\wp(A) \to 2\right) \right) \\ \cong (\dagger) \quad \left(A \times \wp(\mathsf{P}) \times \wp(A)\right) \to 2 \\ \cong (\dagger) \quad A \to \left(\left(\wp(\mathsf{P}) \times \wp(A)\right) \to 2\right) \\ \cong (\ddagger) \quad A \to \wp(\wp(\mathsf{P}) \times \wp(A)) \end{array}$$

In fact, the translations given in Definition 11.3 can be obtained by computing the bijections between  $T_D$  and  $T_K$ , on the basis of those in ( $\dagger$ ) and ( $\ddagger$ ).

**Proposition 11.5** (i) Let  $\mathbb{A} = \langle A, \Delta, \Omega, a_I \rangle$  be a Kripke automaton. Then  $\mathbb{A} \equiv \mathbb{A}^M$ . (ii) Let  $\mathbb{D} = \langle D, \Theta, \Omega, d_I \rangle$  be a disjunctive modal automaton. Then  $\mathbb{D} \equiv \mathbb{D}^K$ .

**Proof.** The proof of this proposition is straightforward. If we merge the two moves of  $\exists$  in each round of the acceptance game for Kripke automata into one, we may in fact show that, for any Kripke model S, the acceptance games  $\mathcal{A}(\mathbb{A}^M, S)$  and  $\mathcal{A}(\mathbb{A}, S)$  are *isomorphic*, and similarly for the acceptance games  $\mathcal{A}(\mathbb{D}^K, S)$  and  $\mathcal{A}(\mathbb{D}, S)$ . QED

## Small model property for Kripke automata

We will now prove the small model property for *Kripke automata*. This framework allows us to prove a result that is quite a bit stronger than just a small model theorem: we may show that, if  $\mathbb{A}$  is a Kripke automaton recognizing a non-empty query, then  $\mathcal{Q}\mathbb{A}$  contains a Kripke model that 'lives inside' or *inhabits*  $\mathbb{A}$ .

**Definition 11.6** Let  $\mathbb{A} = \langle A, \Theta, \Omega, a_I \rangle$  be a Kripke automaton. If S is a subset of A, and  $\sigma : S \to \mathsf{K}S$  is such that  $\sigma(s) \in \Delta(s)$  for all  $s \in S$ , then we say that the Kripke model  $\mathbb{S} = \langle S, \sigma \rangle$  inhabits  $\mathbb{A}$ . When we use this terminology for a pointed Kripke model  $(\mathbb{S}, s)$ , we require in addition that  $s = a_I$ .

The key tool in our proof of the small model property will be the following *satisfiability* game that we may associate with a Kripke automaton. Intuitively the reader may think of this game as the simultaneous projection on  $\mathbb{A}$  of all acceptance games of  $\mathbb{A}$ , as should become clear from the proof of Theorem 11.8 below.

**Definition 11.7** Let  $\mathbb{A} = \langle A, \Delta, \Omega, a_I \rangle$  be a Kripke automaton. Then the satisfiability game  $\mathcal{S}(\mathbb{A})$  is given by Table 25. The winning condition for infinite matches is defined using the priority map for game positions (see the table) as a parity condition.

One last remark before we formulate and prove the main technical result of this section: the proof of this theorem involves a crucial application of the Positional Determinacy of parity games.

Position	Player	Admissible moves	Priority
$a \in A$	Ξ	$\Delta(a)$	$\Omega(a)$
$(c,B) \in KA$	$\forall$	В	0

Table 25: Satisfiability game for Kripke automata

**Theorem 11.8** The following are equivalent, for any Kripke automaton  $\mathbb{A} = \langle A, \Theta, \Omega, a_I \rangle$ : 1)  $\mathcal{Q}(\mathbb{A}) \neq \emptyset$ ;

2)  $a_I \in Win_{\exists}(\mathcal{S}(\mathbb{A}));$ 3)  $\mathbb{A}$  accepts a pointed model inhabiting  $\mathbb{A}$ .

**Proof.**  $[1 \Rightarrow 2]$  Suppose that  $\mathbb{A}$  accepts some pointed model  $(\mathbb{S}, s_0)$ . Then by definition,  $\exists$  has a winning strategy in the acceptance game  $\mathcal{A}(\mathbb{A}, \mathbb{S})@(a_I, s_0)$ . This strategy will be the basis of her winning strategy in the satisfiability game of  $\mathbb{A}$ .

Concretely, in  $\mathcal{S}(\mathbb{A})@a_I$ ,  $\exists$  will maintain the following condition. Put  $a_0 = a_I$ , and let

$$a_0(c_1, B_1)a_1(c_2, B_2)\ldots a_k,$$

be an initial segment of an  $\mathcal{S}(\mathbb{A})$ -match (with  $(c_{i+1}, B_{i+1}) \in \Theta(a_i)$  being the move of  $\exists$  at position  $a_i$ , and  $a_{i+1} \in B_{i+1}$  the next move of  $\forall$ ). Then  $\exists$  sees this match as the projection of a parallel match of  $\mathcal{A}(\mathbb{A}, \mathbb{S})@(a_I, s_0)$  where she plays her winning strategy:

The existence of such a parallel match is easily proved by an inductive argument, of which the base case is immediate by the shape  $(a_I \text{ versus } (a_I, s_0))$  of the initial game positions. Inductively assume that at stage k, the matches of  $\mathcal{S}(\mathbb{A})$  and  $\mathcal{A}(\mathbb{A}, \mathbb{S})$  have arrived at the positions  $a_k$  and  $(a_k, s_k)$  respectively. We will show that there is a way to continue both matches for one round in such a way that the next basic positions are of the form b and (b, t), respectively, for some  $b \in A$  and  $t \in S$ , with the continuation in the acceptance game being guided by  $\exists$ 's winning strategy.

Suppose that  $\exists$ 's winning strategy in the acceptance game tells her to choose position  $((c, B), \sigma(s_k))$ , followed by the relation Z. Then at position  $a_k$  of  $\mathcal{S}(\mathbb{A})$ , we define her strategy to be such that she picks (c, B). Now suppose that in the match of  $\mathcal{S}(\mathbb{A})$ ,  $\forall$  chooses some element  $b \in B$  as the next position. It follows by the assumption that  $\exists$ 's strategy is winning, that  $(c, B) \in \Theta(a_k)$ ,  $c = \sigma_V(s_k)$  and  $(B, R[s_k]) \in \overline{\wp}(Z)$ . Hence there must be an element  $t \in R[s_k]$  such that  $(b, t) \in Z$ ; in the acceptance game, she may look at a continuation of the match where  $\forall$  picks the pair (b, t). In other words, we have proved that  $\exists$  can maintain the parallel match for one more round.

Using this strategy in the satisfiability game will then guarantee her to win the match, since the associated sequence of  $\mathbb{A}$ -states is the same for both matches, and in the  $\mathcal{A}(\mathbb{A}, \mathbb{S})$ -match  $\exists$  plays according to a strategy that was assumed to be winning.

 $[2 \Rightarrow 3]$  Assume that  $\exists$  has a winning strategy in the satisfiability game starting from the initial state  $a_I$  of  $\mathbb{A}$ . Let  $S := \operatorname{Win}_{\exists}(\mathcal{S}(\mathbb{A}))$  be the set of positions in A that are winning for  $\exists$ . The key point of the satisfiability game for Kripke automata is that  $\mathcal{S}(\mathbb{A})$  is a parity game, and so we may without loss of generality assume that this strategy is *positional*, see Theorem ??. In other words, we may represent it as a map  $\sigma : S \to \mathsf{K}A$ . We invite the reader to check that  $\sigma(a) \in \mathsf{K}S$  for all  $a \in S$ . Now define  $\mathbb{S}$  be the Kripke model  $\langle S, \sigma \rangle$ . The map  $\sigma : S \to \mathsf{K}S$  then induces a binary relation  $R \subseteq S \times S$  and a valuation  $V : \mathsf{P} \to \wp(S)$ , viz., the unique R and V such that  $\sigma(s) = (R[s], \sigma_V(s))$ . We claim that  $\mathbb{A}$  accepts  $(\mathbb{S}, a_I)$ .

To see why this is the case, we will prove that  $(a_I, a_I)$  is a winning position in the acceptance game  $\mathcal{A}(\mathbb{A}, \mathbb{S})$ . The winning strategy that we may equip  $\exists$  with in this game is in fact very simple:

- at position (a, s), pick  $(\sigma(a), \sigma(s))$  as the next position if  $a = s \in Win_{\exists}(\mathcal{S}(\mathbb{A}))$ , and choose a random element otherwise;
- at position ((c, B), (c', B')), pick the relation  $\{(b, b) \mid b \in B \cap B'\}$ .

It can be proved that any match of the acceptance game in which  $\exists$  uses this strategy, can be 'projected' onto a match of the satisfiability game in which she plays her winning strategy:

Given the winning conditions of  $\mathcal{A}(\mathbb{A}, \mathbb{S})$  and  $\mathcal{S}(\mathbb{A})$  it is then immediate that the given strategy indeed guarantees that  $\exists$  wins any match starting at position  $(a_I, a_I)$ .

 $|3 \Rightarrow 1|$  This implication is a direct consequence of the definitions. QED

### 11.2 Normal forms and decidability

In this section we will see two more corollaries of the results in the previous chapter.

## Disjunctive normal form

As a first consequence, we now see that every formula of the modal  $\mu$ -calculus can be brought into so-called *disjunctive normal form*. For the definition of the connectives used below we refer to Definition 1.37.

**Definition 11.9** Given a sets P of proposition letters, the set of *disjunctive* modal  $\mu$ -calculus formulas<sup>10</sup> over P is given by the following grammar:

$$\varphi ::= x \mid \perp \mid \top \mid \bigvee \Phi \mid \alpha \bullet \Phi \mid \mu x.\varphi \mid \nu x.\varphi$$

Here x is a variable *not* in P,  $\alpha$  denotes a finite set of literals over P, and  $\Phi$  is a finite collection of disjunctive formulas over P.

<sup>&</sup>lt;sup>10</sup>In this section we work with a variation of the earlier definition: it will be convenient for us here to have  $\top$  and  $\perp$  as *primitive* formulas.

We let  $\mu ML_D(\mathsf{P})$  denote the sentences of this language, that is, the disjunctive formulas  $\varphi$  such that  $FV(\varphi) \subseteq \mathsf{P}$ .

These formula are called disjunctive because the only admissible conjunctions are the special ones of the form  $\alpha \bullet \Phi$ , where  $\alpha$  is a propositional formula (in fact, a conjunction of literals).

**Theorem 11.10** There is an effective algorithm that rewrites a modal fixpoint formula  $\xi \in \mu ML(P)$  into an equivalent disjunctive formula  $\xi^d$  of closure size at most exponential in  $|\xi|$ .

- ▶ proof (based on the results of the previous chapters) to be supplied.
- ▶ size issues to be addressed!

#### Decidability

▶ Intro

**Theorem 11.11** There is an algorithm that decides in linear time (measured in dag-size) whether a given disjunctive formula  $\xi$  is satisfiable or not.

**Proof.** It is easy to see that the proof of this proposition is a direct consequence of the following observations:

- 1.  $\top$  is satisfiable;
- 2.  $\perp$  is not satisfiable;
- 3.  $\bigvee \Phi$  is satisfiable iff some  $\varphi \in \Phi$  is satisfiable;
- 4.  $\alpha \bullet \nabla \Phi$  is satisfiable iff both  $\alpha$  and each  $\varphi \in \Phi$  is satisfiable;
- 5. if  $\mu x.\varphi$  is disjunctive, then it is satisfiable iff  $\varphi[\perp/x]$  is satisfiable;
- 6. if  $\nu x.\varphi$  is disjunctive, then it is satisfiable iff  $\varphi[\top/x]$  is satisfiable.

The proof of these claims is left as an exercise for the reader.

QED

Decidability of the satisfiability problem for modal fixpoint formulas is then an immediate consequence of the previous two results.

**Corollary 11.12** There is an algorithm that decides in elementary time whether a given modal fixpoint formula  $\xi$  is satisfiable or not.

▶ Corollary 11.12 does not provide the best complexity bound for the satisfiability problem for the  $\mu$ -calculus, which can in fact be solved in (singly) exponential time.

 $\triangleleft$ 

## 11.3 Uniform interpolation and bisimulation quantifiers

In this section we will prove that the modal  $\mu$ -calculus enjoys the property of *uniform inter*polation by proving that we can express the so-called *bisimulation quantifiers* in the language.

**Definition 11.13** Given two modal fixpoint formulas  $\varphi$  and  $\psi$ , we say that  $\psi$  is a *(local)* consequence of  $\varphi$ , notation:  $\varphi \models \psi$ , if  $\mathbb{S}, s \Vdash \varphi$  implies  $\mathbb{S}, s \Vdash \psi$ , for every pointed Kripke model  $(\mathbb{S}, s)$ .

A formalism has the (Craig) interpolation property if we can find an interpolant for every pair of formulas  $\varphi$  and  $\psi$  such that  $\varphi \models \psi$ . This interpolant is a formula  $\theta$  such that  $\varphi \models \theta$ and  $\theta \models \psi$ ; but most importantly, the requirement on  $\theta$  is that it may only use proposition letters that occur both in  $\varphi$  and  $\psi$ , or more precisely:  $FV(\theta) \subseteq FV(\varphi) \cap FV(\psi)$ .

▶ why this is an important property

Uniform interpolation is a very strong version of interpolation in which the interpolant  $\theta$  does not depend on the particular shape of one of the formulas, but only on its *vocabulary* (set of free variables). More precisely, we define the following.

**Definition 11.14** Let  $\varphi$  be a modal fixpoint formula, and  $\mathsf{P} \subseteq FV(\varphi)$  be a set of variables. Then a *(right) uniform interpolant* of  $\varphi$  with respect to  $\mathsf{P}$  is a formula  $\theta$  with  $FV(\theta) \subseteq \mathsf{P}$ , such that

$$\varphi \models \psi \text{ iff } \theta \models \psi. \tag{121}$$

for all formulas  $\psi$  with  $FV(\psi) \cap FV(\varphi) \subseteq \mathsf{P}$ .

In words, (121) states that  $\theta$  has exactly the same consequences as  $\varphi$ , at least, if we restrict to formulas  $\psi$  such that all free variables shared by  $\varphi$  and  $\psi$  belong to P.

**Remark 11.15** To justify the terminology 'uniform interpolant', take some formula  $\psi$  with  $FV(\psi) \cap FV(\varphi) \subseteq \mathsf{P}$ . We claim that

$$\varphi \models \psi \text{ implies } \varphi \models \theta \text{ and } \theta \models \psi$$
 (122)

for any uniform interpolant  $\theta$  of  $\varphi$  with respect to P.

To see this, suppose that  $\varphi \models \psi$ , and let  $\theta$  be a uniform interpolant of  $\varphi$  with respect to P. Then we have  $\theta \models \psi$  by (121), so it remains to show that  $\varphi \models \theta$ . But this follows immediately from the fact that by definition we have  $FV(\theta) \cap FV(\varphi) \subseteq \mathsf{P}$ , so that we may apply (121) to  $\theta$  itself (and use that, obviously,  $\theta \models \theta$ ).

**Remark 11.16** Dually, we could have introduced the notion of a *left* uniform interpolant for  $\psi$ , instead of a *right* interpolant for  $\varphi$ . A left interpolant for  $\psi$ , with respect to a set  $\mathsf{P} \subseteq FV(\psi)$  of proposition letters, is a formula  $\chi$  with  $FV(\chi) \subseteq \mathsf{P}$ , and such that  $\varphi \models \psi$  iff  $\varphi \models \chi$ . But since negation is definable in the modal  $\mu$ -calculus as an operation  $\sim : \mu \mathsf{ML}(\mathsf{P}) \rightarrow$  $\mu \mathsf{ML}(\mathsf{P})$  and so we have  $\varphi \models \psi$  iff  $\sim \psi \models \sim \varphi$ , it is not hard to see that if  $\theta$  is a (right) uniform interpolant for  $\psi$ , then its negation  $\sim \theta$  is a left interpolant for  $\psi$ . In other words, since our language is closed under classical negation, requiring that every formula has a right uniform interpolant is equivalent to requiring that every formula has a left uniform interpolant. The following theorem states that uniform interpolants exist in the modal  $\mu$ -calculus.

**Theorem 11.17 (Uniform Interpolation)** Let  $\varphi$  be a modal fixpoint formula, and let P be a set of variables such that  $P \subseteq FV(\varphi)$ . Then  $\varphi$  has a uniform interpolant with repect to P.

The proof consists of showing that the modal  $\mu$ -calculus can express the so-called *bisim*ulation quantifiers.

**Definition 11.18** Given a proposition letter q, the *bisimulation quantifier*  $\exists q$  is an operator with the following semantics:

$$\mathbb{S}, s \Vdash \exists q.\varphi \text{ iff } \mathbb{S}', s' \Vdash \varphi, \text{ for some pointed model } \mathbb{S}', s' \leftrightarrows_{\mathsf{R} \setminus q} \mathbb{S}, s,$$
(123)

where S is some Kripke model over a set R of proposition letters, and  $\bigoplus_{R\setminus q}$  is the bisimilarity relation 'up to q', that is, we only require the condition (prop) of Definition 1.19 to hold for proposition letters  $p \in R \setminus q$ .

The bisimulation quantifier  $\exists q$  is a second-order existential quantifier, but nonstandard in the sense that it does not quantify over subsets of the actual model  $\mathbb{S}$ , but rather over subsets of possibly distinct (but bisimilar-up-to-q) models. For instance, if s is a state in  $\mathbb{S}$  with one single successor, then obviously the formula  $\exists q(\Diamond q \land \Diamond \overline{q})$  would be false if we had to interpret q as a subset of S. However, taking a bisimilar pointed model ( $\mathbb{S}', s'$ ) such that s' has two successors, we can easily interpret q as a subset of S' such that the formula  $\Diamond q \land \Diamond \overline{q}$  becomes true at s'. Similarly, the formula  $\exists q(q \land \Box \overline{q})$  holds at any point in any Kripke model.

The main result underlying the proof of Theorem 11.17 is that the bisimulation quantifiers are *definable* in the modal  $\mu$ -calculus. The following notation will be convenient.

**Convention 11.19** Where P is a set of proposition letters, and q is a proposition letter (which may or may not belong to P), we write  $P \setminus q$  rather than  $P \setminus \{q\}$ .

**Theorem 11.20** For any set P of proposition letters, and any proposition letter q, there is a map

$$\widetilde{\exists}q:\mu\mathrm{ML}_{\mathsf{D}}(\mathsf{P})\to\mu\mathrm{ML}_{\mathsf{D}}(\mathsf{P}\setminus q)$$

such that for any formula  $\varphi \in \mu \mathbb{ML}_{\mathsf{D}}(\mathsf{P})$ , we have  $FV(\widetilde{\exists}q.\varphi) = FV(\varphi) \setminus q$ , and the semantics of  $\widetilde{\exists}q.\varphi$  satisfies (123), for any Kripke model over a set of proposition letters  $\mathsf{R} \supseteq \mathsf{P}$ .

The proof of Theorem 11.20 crucially involves *disjunctive* modal automata. Before going into the details, there is a technicality that we need to get out of the way.

**Remark 11.21** Let  $\mathbb{A} = \langle A, \Theta, \Omega, a_I \rangle$  be a modal automaton over some set P of proposition letters, and let  $\mathbb{S} = (S, R, V)$  be a Kripke model over some, possibly larger, set R. Then strictly speaking the acceptance game  $\mathcal{A}(\mathbb{A}, \mathbb{S})$  is not well-defined since the domain of the transition map  $\Theta$  is of the form  $\mathsf{Dom}(\Theta) = A \times \wp(\mathsf{P})$ , while the range of the colouring map  $\sigma_V$  of S is the set  $\mathsf{Ran}(\sigma_V) = \wp(\mathsf{R})$ . But clearly we can take care of this mismatch by working with the map  $\Theta_{\mathsf{R}} : A \times \wp(\mathsf{R}) \to \mathsf{1ML}(A)$  given by

$$\Theta_{\mathsf{R}}(a,c) := \Theta(a,c \cap \mathsf{P}).$$

In the sequel we will largely ignore this issue.

We now turn to the details of the proof of Theorem 11.20. Because of the existence of truthpreserving translations between formulas and automata, it suffices to provide a construction on modal automata that instantiates the bisimulation quantifier, and because of the Simulation Theorem it suffices to define this construction for disjunctive modal automata.

**Definition 11.22** Let P be a set of proposition letters and let q be a proposition letter (possibly but not necessarily in P). Let  $\mathbb{A} = \langle A, \Theta, \Omega, a_I \rangle$  be a disjunctive modal automaton over the set P. We abbreviate  $C := \wp(\mathsf{P})$  and  $C^- := \wp(\mathsf{P} \setminus \{q\})$ .

Now we define the modal automaton  $\exists q. \mathbb{A}$  as the structure  $\exists q. \mathbb{A} := \langle A, \Theta^{\pm q}, \Omega, a_I \rangle$ , where

$$\Theta^{\pm q}(a,c) := \Theta(a,c \setminus \{q\}) \lor \Theta(a,c \cup \{q\})$$

defines the transition map  $\Theta^{\pm q} : A \times C^- \to 1DML(A)$ .

The main technical result that we will prove is the following. Recall from Definition 10.16 that we write  $\mathbb{S}, s_I \Vdash_s \mathbb{A}$  in case  $\exists$  has a functional strategy in the game  $\mathcal{A}(\mathbb{A}, \mathbb{S})@(a_I, s_I)$ .

**Proposition 11.23** Let  $\mathbb{A}$  be a disjunctive modal P-automaton, and let  $\mathbb{S}$  be a Kripke model over some set  $\mathbb{R} \supseteq \mathbb{P}$ . Then the following are equivalent, for any state  $s_I \in \mathbb{S}$ : 1)  $\mathbb{S}, s_I \Vdash_s \widetilde{\exists} q.\mathbb{A};$ 2)  $\mathbb{S}[q \mapsto Q], s_I \Vdash_s \mathbb{A}$ , for some subset  $Q \subseteq S$ .

**Proof.** We only consider the case where  $\mathsf{R} = \mathsf{P}$ , leaving it for the reader to extend the result to the more general case (cf. Remark 11.21). Fix a disjunctive P-automaton  $\mathbb{A} = \langle A, \Theta, \Omega, a_I \rangle$ and an R-model  $\mathbb{S} = (S, R, V)$ ; to simplify notation we will write  $c_t := \sigma_V(t)$ , for an arbitrary point  $t \in S$ . Similarly, we will write  $c - q := c \setminus \{q\}$  and  $c + q := c \cup \{q\}$  for an arbitrary colour  $c \in \wp(\mathsf{P})$ . Furthermore, we will use the one-step presentation of the acceptance game, as in Table 21.

For the direction  $1) \Rightarrow 2$  of the Proposition, assume that  $\mathbb{S}, s_I \Vdash_s \widetilde{\exists} q.\mathbb{A}$ . In other words,  $\exists$  has a *functional* positional strategy f which is winning in the game  $\mathcal{A}(\widetilde{\exists} q.\mathbb{A}, \mathbb{S})@(a_I, s_I)$ . Abbreviate  $\mathcal{A} := \mathcal{A}(\widetilde{\exists} q.\mathbb{A}, \mathbb{S})$ .

Let  $U \subseteq S$  be the set of points t in S such that, for some state  $a \in A$ , the position (a, t)is f-reachable in  $\mathcal{A}@(a_I, s_I)$ . It follows from functionality of f that for every  $t \in U$  there is a unique such state in  $\mathbb{A}$ ; we will denote this state as  $a_t$ . Furthermore, since f is a winning strategy in  $\mathcal{A}@(a_I, s_I)$ , every position of the form  $(a_t, t)$  is winning for  $\exists$ , and so by legitimacy of f, the marking  $m_t : R[t] \to \wp(A)$  picked by f at this position is such that

$$(R[t], m_t) \Vdash^1 \Theta^{\pm q}(a_t, c_t).$$

$$(124)$$

 $\triangleleft$ 

Given that  $\Theta^{\pm q}(a_t, c_t) = \Theta(a_t, c_t - q) \vee \Theta(a_t, c_t + q)$ , this observation provides the set  $Q \subseteq S$  that we are looking for:

$$Q := \{ t \in U \mid (R[t], m_t) \Vdash^1 \Theta(a_t, c_t + q) \}.$$

We claim that  $\mathbb{S}[q \mapsto Q], s_I \Vdash_s \mathbb{A}$ , and to show this, we define the following positional strategy  $f_Q$  for  $\exists$  in  $\mathcal{A}_Q := \mathcal{A}(\mathbb{A}, \mathbb{S}[q \mapsto Q])$ . At a position  $(a, t) \in A \times S$ ,  $\exists$  will play as follows:

- in case  $t \in U$  and  $a = a_t$ , she picks the marking  $m_t$ ;
- in all other cases she picks a random marking.

We first show that for each  $t \in U$  and  $a = a_t$  this strategy provides a legitimate move in  $\mathcal{A}_Q$ , that is,

$$(R[t], m_t) \Vdash^1 \Theta(a_t, \sigma_{V[q \mapsto Q]}(t)).$$
(125)

To see this, make the following case distinction:

- If  $(R[t], m_t) \Vdash^1 \Theta(a_t, c_t + q)$  then by definition of Q we find  $t \in Q$ . This means that  $\sigma_{V[q \mapsto Q]}(t) = \sigma_V(t) \cup \{q\} = c_t + q$ . In other words, (125) holds indeed.
- If, on the other hand,  $(R[t], m_t) \not\Vdash^1 \Theta(a_t, c_t + q)$  then by definition of Q we find  $t \notin Q$ . Furthermore, by (124) and the definition of  $\Theta^{\pm q}$  it must be the case that  $(R[t], m_t) \Vdash^1 \Theta(a_t, c_t - q)$ . But since  $t \notin Q$  we have  $\sigma_{V[q \mapsto Q]}(t) = \sigma_V(t) \setminus \{q\} = c_t - q$ , so that again we obtain (125).

It remains to show that  $f_Q$  is functional, and winning for  $\exists$  in  $\mathcal{A}_Q(a_I, s_I)$ , but this is in fact easy. The point is that at any position of the form  $(a_t, t)$  the strategies f and  $f_Q$ prescribe the same move, viz.,  $m_t$ , and that at the position  $m_t$  the moves of  $\forall$  in  $\mathcal{A}$  and  $\mathcal{A}_Q$ are the same. From this it follows that every position for  $\exists$  that is reachable in an  $f_Q$ -guided match of  $\mathcal{A}_Q(a_I, s_I)$  is of the form  $(a_t, t)$  (with  $t \in U$ ), and so by our previous claim about the legitimacy of  $f_Q$  at such positions,  $f_Q$  is a surviving strategy. Now consider an  $f_Q$ -guided full match of  $\mathcal{A}_Q(a_I, s_I)$ ; this very same match is also an f-guided match of  $\mathcal{A}$ , and hence won by  $\exists$  — after all we assumed that f is a winning strategy for  $\exists$  in  $\mathcal{A}(a_I, s_I)(a_I, s_I)$ , and the winning conditions in  $\mathcal{A}_Q$  and  $\mathcal{A}$  are the same. In other words, every  $f_Q$ -guided full match of  $\mathcal{A}_Q(a_I, s_I)$  is won by  $\exists$ . Finally, since f is a functional strategy, so is  $f_Q$ . This finishes the proof that  $1 \rightarrow 2$ ).

The proof of the opposite implication,  $2) \Rightarrow 1$ ), is similar; we omit the details. QED

From this, Theorem 11.20 is almost immediate.

**Proof of Theorem 11.20.** Let P and q be a set of proposition letters and a proposition letter, respectively, let A be a disjunctive modal automaton over P, and let  $(\mathbb{S}, r)$  be a pointed model over a set R of proposition letters such that  $P \subseteq R$ . It suffices to show that

$$\mathbb{S}, r \Vdash \exists q. \mathbb{A} \text{ iff } \mathbb{S}', r' \Vdash \mathbb{A}, \text{ for some } (\mathbb{S}', r') \text{ with } \mathbb{S}, r \rightleftharpoons_{\mathsf{R} \setminus q} \mathbb{S}', r'.$$
(126)

But since  $\mathbb{A}$  is disjunctive, it is easy to see that  $\exists q.\mathbb{A}$  is disjunctive as well, and so it follows from Theorem 10.18 that

$$\mathbb{S}, r \Vdash \widetilde{\exists} q.\mathbb{A} \text{ iff } \mathbb{S}', r' \Vdash_s \widetilde{\exists} q.\mathbb{A}, \text{ for some } (\mathbb{S}', r') \text{ with } \mathbb{S}, r \rightleftharpoons_{\mathsf{R} \setminus q} \mathbb{S}', r'.$$
(127)

Combining this with Proposition 11.23 we find

$$S, r \Vdash \widetilde{\exists} q. \mathbb{A} \text{ iff } S'[q \mapsto Q], r' \Vdash_s \mathbb{A}, \text{ for some } (S', r') \text{ with } S, r \rightleftharpoons_{\mathsf{R} \setminus q} S', r' \text{ and some } Q \subseteq S'.$$
(128)  
Now it is obvious that  $S'[q \mapsto Q], r' \rightleftharpoons_{\mathsf{R} \setminus q} S', r'.$  But then (126) is immediate. QED

Finishing this section, we show how to derive the uniform interpolation property from the definability of the bisimulation quantifiers.

**Proof of Theorem 11.17.** Fix the formula  $\varphi$  and the set P, and let  $q_1, \ldots, q_n$  enumerate the free variables of  $\varphi$  that are *not* in P, that is,  $\{q_1, \ldots, q_n\} = FV(\varphi) \setminus \mathsf{P}$ . We claim that the formula  $\exists q_1 \cdots \exists q_n.\varphi$  is the required (right) uniform interpolant of  $\varphi$  with respect to P.

To prove this, take an arbitrary formula  $\psi$  such that  $FV(\psi) \cap FV(\varphi) \subseteq \mathsf{P}$ . Clearly this implies that no  $q_i$  is a free variable of  $\psi$ . We first show that

$$\varphi \models \widetilde{\exists} q_1 \cdots \widetilde{\exists} q_n . \varphi.$$

To see this, let  $(\mathbb{S}, s)$  be some pointed Kripke model (over some set  $\mathbb{R} \supseteq FV(\varphi)$ ) such that  $\mathbb{S}, s \Vdash \varphi$ . Since we obviously have that  $\mathbb{S}, s \hookrightarrow_{\mathbb{R}\setminus q} \mathbb{S}, s$  for any proposition letter q, it easily follows that  $\varphi \models \exists q_1 \cdots \exists q_n \varphi$ . This takes care of the right-to-left direction from (121).

For the opposite direction of (121), assume that  $\varphi \models \psi$ , and let  $(\mathbb{S}, s)$  be a pointed Kripke model such that  $\mathbb{S}, s \Vdash \tilde{\exists} q_1 \cdots \tilde{\exists} q_n \cdot \varphi$ . It follows that there is a sequence  $(\mathbb{S}_i, s_i)_{0 \leq i \leq n}$ of pointed models such that  $(\mathbb{S}, s) = (\mathbb{S}_0, s_0), \mathbb{S}_n, s_n \Vdash \varphi$ , and  $\mathbb{S}_i, s_i \rightleftharpoons_{\mathbb{R} \setminus q_{i+1}} \mathbb{S}_{i+1}, s_{i+1}$  for all i with  $0 \leq i < n$ . Then by assumption it follows from  $\mathbb{S}_n, s_n \Vdash \varphi$  that  $\mathbb{S}_n, s_n \Vdash \psi$ . But since none of the proposition letters  $q_i$  is free in  $\psi$ , step by step applying the bisimulation invariance of the modal  $\mu$ -calculus we may show that each pointed model  $\mathbb{S}_i, s_i$  satisfies  $\psi$ . In particular, we find that  $\mathbb{S}, s \Vdash \psi$ , as required. QED

### Notes

The decidability of the satisfiability problem of the modal  $\mu$ -calculus was first proved by Kozen and Parikh [11] via a reduction to SnS. Emerson & Jutla [?] established the EXPTIME-completeness of this problem. The finite model property was proved by Kozen [?].

Uniform interpolation of the modal  $\mu$ -calculus was proved by D'Agostino & Hollenberg [?], who established some other model-theoretic results as well.

#### Exercises

**Exercise 11.1** Let  $\gamma$  be some disjunctive fixed point formula.

(a) Show that  $\mu x.\gamma$  is satisfiable iff  $\gamma[\perp/x]$  is satisfiable.

- (b) Show that  $\nu x.\gamma$  is satisfiable iff  $\gamma[\top/x]$  is satisfiable.
- (c) Do the above statements hold for arbitrary fixed point formulas as well?

**Exercise 11.2** Prove the left-to-right direction of (136) in Proposition 12.28.

Exercise 11.3 Is disjunctivity of the automaton A needed in the proof of Proposition 11.23?

Exercise 11.4 (PDL + bisimulation quantifier) Consider a setting with finitely many atomic actions. Let PDL+ $\tilde{\exists}$  be the extension of propositional dynamic logic with (explicit) bisimulation quantifiers. Show that there is a (truth-preserving) translation from the modal  $\mu$ -calculus to PDL+ $\tilde{\exists}$ .

## 12 Expressive completeness

In this chapter we compare the expressive power of the modal  $\mu$ -calculus to that of monadic second-order logic. The key result that we will prove is that the modal  $\mu$ -calculus has the same expressive power as the bisimulation invariant fragment of monadic second-order logic, in brief:

$$\mu \mathsf{ML} \equiv \mathsf{MSO}/ \mathcal{L}. \tag{129}$$

In fact, Theorem 12.21, the actual result that we are going to prove, is a bit stronger than (129).

Our proof will be automata-theoretic in nature: after discussing two different (but equivalent) versions of monadic second-order logic in section 12.1, we show in section 12.2 that on tree models, MSO has the same expressive power as the class Aut(1FOE) of automata over the one-step logic 1FOE. Since the modal  $\mu$ -calculus corresponds to the class Aut(1FO), we will prove (129) in section 12.3 via a comparison of the one-step languages 1FOE and 1FO.

### 12.1 Monadic second-order logic

Second-order logic is the extension of first-order logic where quantification is allowed, not only over individuals, but also over relations on the domain. In *monadic* second-order logic, this second-order quantification is restricted to unary relations, that is, subsets of the domain. The syntax of monadic second-order logic is usually defined as the extension of that of first-order logic by second-order quantifiers of the form  $\exists p/\forall p$ , where p is a monadic predicate symbol.

**Definition 12.1** Given a set D of atomic actions, a set IVar of individual variables and a set Prop of set variables, we define the language  $MSO_D^2$  as follows:

$$\varphi ::= x \doteq y \mid R_d x y \mid p(x) \mid \neg \varphi \mid \varphi \lor \varphi \mid \exists x.\varphi \mid \exists p.\varphi$$

Here x and y are variables from IVar, p is a variable from P, and  $d \in D$  is an atomic action.

We let  $MSO_D^2(X, P)$  denote the set of  $MSO_D^2$ -formulas  $\varphi$  of which all individual free variables are from X and all free set variables are from P. In case X is a singleton  $\{x\}$ , we write  $MSO_D^2(x, P)$  rather than  $MSO_D^2(\{x\}, P)$ 

This semantics of this language is completely standard, with  $\exists x$  denoting first-order quantification (that is, quantification over individual states), and  $\exists p$  denoting monadic second-order quantification (that is, quantification over sets of states).

It turns out, however, that for a nice inductive translation of *MSO* to automata, it is more convenient to use a slightly nonstandard version of *MSO* which is *single-sorted* in the sense that it only admits s econd-order variables, not first-order ones. Quantification over individuals can then be simulated by quantification over singleton sets. In addition, to facilitate the comparison with modal languages, which are interpreted in *pointed* Kripke models, we need to install a feature in the language that allows access to the designated or actual world of the Kripke model. **Definition 12.2** Given a set D of atomic actions, we define the language of *monadic second*order logic  $MSO_D$  as follows:

$$\varphi ::= p \sqsubseteq q \mid R_d p q \mid \Downarrow p \mid \neg \varphi \mid \varphi \lor \varphi \mid \exists p.\varphi,$$

where p and q are propositional variables from P. We let  $MSO_D(P)$  denote the set of  $MSO_D$ -formulas of which the free variables are from P.

**Definition 12.3** Given a Kripke model  $\mathbb{S} = \langle S, V, R \rangle$ , and a designated point  $s \in S$ , we define the semantics of MSO as follows:

 $\begin{array}{lll} \mathbb{S},s \models p \sqsubseteq q & \text{if} \quad V(p) \subseteq V(q) \\ \mathbb{S},s \models R_d pq & \text{if} \quad \text{for all } t \in V(p) \text{ there is a } u \in V(q) \text{ with } R_d tu \\ \mathbb{S},s \models \forall p & \text{if} \quad V(p) = \{s\} \\ \mathbb{S},s \models \neg \varphi & \text{if} \quad \mathbb{S},s \not\models \varphi \\ \mathbb{S},s \models \varphi \lor \psi & \text{if} \quad \mathbb{S},s \models \varphi \text{ or } \mathbb{S},s \models \psi \\ \mathbb{S},s \models \exists p.\varphi & \text{if} \quad \mathbb{S}[p \mapsto X], s \models \varphi \text{ for some } X \subseteq S. \end{array}$ 

An MSO-formula  $\varphi$  is *bisimulation invariant* if  $\mathbb{S}, s \hookrightarrow \mathbb{S}', s'$  implies that  $\mathbb{S}, s \models \varphi \Leftrightarrow \mathbb{S}', s \models \varphi$ .  $\triangleleft$ 

**Remark 12.4** In fact, one may think of the formalism as a *first-order* logic of which the intended models are *power structures* of the form  $\langle \wp(S), \subseteq, \vec{R}, \{s\}\rangle$ , where  $R_d(Y, Z)$  iff for all  $y \in Y$  there is a  $z \in Z$  such that  $R_d y z$ .)

It is not too hard to see that the two languages are in fact equivalent.

**Theorem 12.5** There are effective procedures transforming a formula in  $MSO^2(x, P)$  into an equivalent MSO(P)-formula, and vice versa:

$$MSO^2 \equiv MSO.$$

To start with, there is a straightforward, inductively defined translation  $(\cdot)' : MSO_{D}(\mathsf{P}) \to MSO_{D}^{2}(x,\mathsf{P})$  such that

$$\mathbb{S}, s \models \varphi \text{ iff } \mathbb{S} \models \varphi'[s],$$

for all formulas  $\varphi \in MSO_D(P)$  and all pointed Kripke models S. The only interesting clause in the inductive definition of this translation concerns the  $\Downarrow$ -connective, for which we set

$$(\Downarrow p)' := \forall y (p(y) \leftrightarrow y \doteq x).$$

For the opposite direction, the key observation is that MSO can interpret  $MSO^2$  by encoding individual variables as set variables denoting *singletons*. To understand how this works, we need to have a closer look at the semantics. Formulas of the language  $MSO^2$  are interpreted over Kripke models S with an *assignment*, that is, a map  $\alpha : IVar \to S$  interpreting the individual variables as elements of S. But then we can encode such an  $MSO^2$ -model S = (S, R, V) with assignment  $\alpha$ , as the MSO-model  $S^{\alpha} := (M, R, V^{\alpha})$  over  $Prop \cup IVar$ , where  $V^{\alpha}(p) := V(p)$  if p is a set variable, and  $V^{\alpha}(x) := {\alpha(x)}$  if x is an individual variable. Lectures on the modal  $\mu$ -calculus

**Proposition 12.6** There is a translation  $(\cdot)^t : MSO_D^2(X, P) \to MSO_D(P \uplus X)$  such that

$$\mathbb{S} \models \varphi[\alpha] \text{ iff } \mathbb{S}^{\alpha} \models \varphi^t \tag{130}$$

for all  $\varphi \in MSO_D^2(X, P)$ , all Kripke models  $\mathbb{S} = (S, R, V)$  and all assignments  $\alpha : X \to S$ .

As a corollary, for all  $\varphi \in MSO_D^2(x, \mathsf{P})$  and all pointed Kripke models  $(\mathbb{S}, s)$  we obtain

$$\mathbb{S} \models \varphi[s] \text{ iff } \mathbb{S}, s \models \forall x. (\Downarrow x \to \varphi^t).$$
(131)

**Proof.** The translation crucially involves the MSO-formulas empty(p) and sing(p) given by

$$\begin{array}{lll} \mathtt{empty}(p) & := & \forall q \ (p \sqsubseteq q) \\ \mathtt{sing}(p) & := & \forall q \ (q \sqsubseteq p \rightarrow (\mathtt{empty}(q) \lor p \sqsubseteq q)). \end{array}$$

It is not hard to prove that these formulas hold in S iff, respectively, V(p) is empty and V(p) is a singleton.

With these formulas defined, we can now inductively fix the translation as follows:

It is a routine exercise to verify (130), so we leave the details for the reader. Similarly, the proof of (131) is immediate by (130) and the definitions of the semantics of  $\Downarrow$ . QED

Note that the translation  $(\cdot)^t$  given in the proof of Proposition 12.6 does not involve the connective  $\Downarrow$ . The only use of  $\Downarrow$  in this setting is to mark the designated node of a *pointed* Kripke model.

## 12.2 Automata for monadic second-order logic

The aim of this section is to provide an automata-theoretic perspective on monadic secondorder logic. That is, we will provide a construction transforming an arbitrary MSO-formula  $\varphi$ into an automaton  $\mathbb{B}_{\varphi}$  that is equivalent to  $\varphi$ , at least, if we confine attention to tree models. In fact, we will encounter various kinds of automata, all corresponding to MSO-formulas, and all taking some fragment of *monadic first-order logic* as the co-domain of their transition map, as in Definition 10.26 and Definition 10.27.

Recall that the set MFOE(A) of monadic first-order formulas over A is given by the following grammar:

 $\alpha ::= \top \mid \perp \mid a(x) \mid \neg a(x) \mid x \doteq y \mid x \neq y \mid \alpha \lor \alpha \mid \alpha \land \alpha \mid \exists x.\alpha \mid \forall x.\alpha$ 

where  $a \in A$  and x, y are first-order (individual) variables, and that MFO(A) is the set of MFOE(A)-formulas without occurrences of identity formulas (or their negations). Recall as

Position	Player	Admissible moves
$(a,s) \in A \times S$	Ξ	$\{U: A \to \wp(R(s)) \mid (R(s), U) \models \Theta(a, \sigma_V(s))\}$
$U: A \to \wp(S)$	$\forall$	$\{(b,t) \mid t \in U(b)\}$

Table 26: Acceptance game for MSO-automata

well that 1FOE(A) and 1FO(A) are the one-step languages consisting of the sentences of, respectively, MFOE(A) and MFO(A), where each monadic predicate  $a \in A$  occurs only positively. It will be convenient in this section to present one-step models using valuations rather than markings; that is, a *one-step model* will be denoted as a pair (Y, V) consisting of some set Yand an A-valuation  $V : A \to \wp(Y)$ .

**Definition 12.7** An *MSO-automaton* over a set P of proposition letters is nothing but a 1F0E-automaton over P, that is, a quadruple  $\mathbb{A} = \langle A, \Theta, \Omega, a_I \rangle$ , where A,  $a_I$  and  $\Omega$  are as usual, and  $\Theta$  is a map  $\Theta : A \times \wp(\mathsf{P}) \to \mathsf{1F0E}(A)$ .

The acceptance game of such an automaton with respect to a Kripke model S is given in Table 12.2. The winning conditions for both finite and infinite matches are as usual.

In words, the acceptance game proceeds as follows. At a basic position (a, s),  $\exists$  chooses a valuation U interpreting each 'predicate'  $a \in A$  as a subset U(a) of the set R(s) of successors of s. In this choice, she is bound by the condition that the sentence  $\Theta(a, \sigma_V(s))$  must be *true* in the resulting A-structure (R(s), U). Once chosen, this map U itself determines the next position of the match. As a position, U belongs to player  $\forall$ , and all he has to do is to choose a pair (b, t) such that  $t \in U(b)$ . This pair (b, t) is then the next basic position of the match.

The link with modal automata is given by Proposition 10.31, stating that, seen as one-step languages, 1FO is equivalent to 1ML. From this we obtain the equivalence in expressive power of the automata classes Aut(1FO) and Aut(1ML), which in its turn entails the following.

**Theorem 12.8** There are effective procedures transforming a  $\mu$ -calculus formula into an equivalent MSO-automaton in Aut(1F0), and vice versa:

$$\mu$$
ML  $\equiv Aut(1FO).$ 

The main result of this section states a very similar result for MSO and arbitrary MSO-automata, if we confine our attention to *tree models*:

**Theorem 12.9** There are effective procedures transforming an MSO-formula  $\xi$  into an MSOautomaton  $\mathbb{A}$ , and vice versa, such that the corresponding formula  $\xi$  and automaton  $\mathbb{A}$  are equivalent on the class of tree models:

$$MSO \equiv Aut(1FOE)$$
 (on tree models).

Note that on *arbitrary* models, monadic second-order logic can express properties that cannot be captured by *MSO*-automata. For instance, it is easy to write an MSO-formula

stating that the designated point of a Kripke model lies on a cycle, but there is no MSOautomaton that recognizes exactly the class of pointed Kripke models with this property.

We will prove the two directions in the statement of Theorem 12.9 separately. Leaving the transformation of automata to monadic second-order formulas to the end of the section, we first concentrate on the opposite direction.

**Proposition 12.10** There is an effective procedure transforming a formula  $\varphi \in MSO(P)$  into an MSO-automaton  $\mathbb{B}_{\varphi}$  over P that is equivalent to  $\varphi$  over the class of tree models. That is:

$$\mathbb{S}, r \models \varphi \; iff \; \mathbb{B}_{\varphi} \; accepts \; (\mathbb{S}, r). \tag{132}$$

for any tree model S with root r.

We will prove Proposition 12.10 by induction on the complexity of MSO-formulas. The proposition below takes care of the atomic case.

**Proposition 12.11** Let  $\varphi$  be one of the atomic MSO-formulas: Rpq,  $p \sqsubseteq q$ , or  $\Downarrow p$ . Then there is an MSO-automaton  $\mathbb{B}_{\varphi}$  that is equivalent to  $\varphi$  on tree models.

**Proof.** We restrict attention to the formula Rpq, leaving the other cases as an exercise for the reader. The automaton  $\mathbb{B}_{Rpq}$  is defined as the structure  $(\{a_0, a_1\}, \Theta, \Omega, a_0)$ , where  $\Theta$  is given by putting:

$$\begin{split} \Theta(a_0,c) &:= \begin{cases} \exists y \left( a_1(y) \land \forall z \left( z \neq y \to a_0(z) \right) \right) & \text{if } p \in c \\ \forall z \, a_0(z) & \text{otherwise} \end{cases} \\ \Theta(a_1,c) &:= \begin{cases} \bot & \text{if } q \notin c \\ \exists y \left( a_1(y) \land \forall z \left( z \neq y \to a_0(z) \right) \right) & \text{if } q \in c \text{ and } p \in c \\ \forall z \, a_0(z) & \text{otherwise} \end{cases}$$

Furthermore,  $\Omega$  is defined via  $\Omega(a_i) := 0$  for each  $a_i$  — as a consequence,  $\exists$  wins all infinite games. We leave it for the reader to verify that this automaton is of the right shape, and that it is indeed equivalent to the formula Rpq on tree models. QED

For the inductive step of the argument, there are three cases to consider, corresponding to, respectively, the connectives  $\vee$  and  $\neg$ , and the (second-order) existential quantification. It turns out that the first two cases are relatively easy to handle, cf. Proposition 10.38. To take care of the existential quantification however, we need to work with *nondeterministic* automata, in which every formula  $\Theta(a, c)$  has been brought into a certain normal form. Fortunately, we can prove a simulation theorem for MSO-automata, implying that we may transform any MSO-automaton into an equivalent nondeterministic one. We need some definitions on these normal forms of 1F0E-formulas.

**Definition 12.12** Fix a set A of propositional variables. We introduce some abbreviations for MFOE-formulas:

$$\texttt{diff}(y_1, \dots, y_n) := \bigwedge \{ y_i \neq y_j \mid 1 \le i < j \le n \},$$

Expressive Completeness

and, for a set  $B \subseteq A$ :

$$\tau_B(x) := \bigwedge_{a \in B} a(x).$$

Now define the following MFOE-sentences:

$$\begin{array}{lll} \chi^{\equiv}_{\overline{B},\overline{C}} &:= & \exists y_1 \cdots y_n \left( \mathtt{diff}(\overline{y}) \land \bigwedge_i \tau_{B_i}(y_i) \land \forall z \left( \mathtt{diff}(\overline{y},z) \to \bigvee_j \tau_{C_j}(z) \right) \right) \\ \chi_{\overline{B},\overline{C}} &:= & \exists y_1 \cdots y_n \left( \bigwedge_i \tau_{B_i}(y_i) \land \forall z \bigvee_j \tau_{C_j}(z) \right) \end{array}$$

where  $\overline{B} = B_1, \ldots, B_n$  and  $\overline{C} = C_1, \ldots, C_m$  are two sequences of subsets of A.

Sentences of the form  $\chi^{=}(\overline{B}, \overline{C})$  are said to be in *basic form*, and in *special basic form* in case each  $B_i$  and  $C_j$  is a singleton. The sets of these formulas are denoted as BF(A) and SBF(A), respectively.

In words, the formula  $\operatorname{diff}(y_1, \ldots, y_n)$  expresses that the variables  $y_1, \ldots, y_n$  refer to n distinct objects of the domain. The formula  $\tau_B(x)$  can be seen to state that x realises the type B, that is: it satisfies all predicates a in B. The formula  $\chi_{\overline{B},\overline{C}}^{=}$  expresses the existence of n distinct objects realising the B-types, with all other objects realising one of the C-types. This formula is (equivalent to) the formula  $\forall z \bigvee_j \tau_{C_j}(z)$  in the special case where n = 0, and, in case m = 0 as well, to the formula  $\forall z \perp$  (which holds in the empty model only). As a simplified version of  $\chi_{\overline{B},\overline{C}}^{=}$ , the sentence  $\chi_{\overline{B},\overline{C}}$  states that all types in  $\overline{B}$  are witnessed by some object, while every object satisfies some C-type. Note that for the latter reason,  $\chi_{\overline{B},\overline{C}}$  is generally not a semantics consequence of  $\chi_{\overline{B},\overline{C}}^{=}$ . Finally, observe that  $\chi_{\overline{B},\overline{C}}^{=}$  and  $\chi_{\overline{B},\overline{C}}$  are positive sentences, and hence, one-step formulas in 1FOE and 1FO, respectively.

Using these normal forms, we can now define the notion of a nondeterministic MSO-automaton.

**Definition 12.13** An *MSO*-automaton  $\mathbb{A} = \langle A, \Theta, \Omega, a_I \rangle$  is called *nondeterministic* if  $\mathsf{Ran}(\Theta) \subseteq \mathsf{Dis}(\mathsf{SBF}(A))$ , that is, every formula  $\Theta(a, c)$  is a disjunction of special basic formulas.

Nondeterministic automata are of interest because they admit functional strategies — in tree models, that is. As in Definition 10.16, we call a strategy f for  $\exists$  in the acceptance game  $\mathcal{A}(\mathbb{A}, \mathbb{S})@(a_I, r)$  functional if for every  $s \in S$  there is at most one  $a \in A$  such that the position (a, s) is reachable in an f-guided match of  $\mathcal{A}(\mathbb{A}, \mathbb{S})@(a_I, r)$ . In case  $\exists$  has a functional strategy which is in addition winning, we write  $\mathbb{S}, r \Vdash_s \mathbb{A}$ . The following proposition states that on tree models, we may always assume that winning strategies are functional.

**Proposition 12.14** Let  $\mathbb{A}$  be a nondeterministic MSO-automaton, and let  $\mathbb{S}$  be a tree-based Kripke model with root r. Then  $\mathbb{S}, r \Vdash \mathbb{A}$  iff  $\mathbb{S}, r \Vdash_s \mathbb{A}$ .

As a corollary, nondeterministic *MSO*-automata are closed under existential second-order quantification.

**Corollary 12.15** Let  $\mathbb{D} = \langle D, \Delta, \Omega, d_I \rangle$  be a nondeterministic MSO-automaton over the set  $\mathbb{P} \cup \{p\}$ . Then there is a nondeterministic automaton  $\mathbb{D}^{\exists p}$  over  $\mathbb{P}$ , such that for all tree models  $(\mathbb{S}, r)$ :

$$\mathbb{D}^{\exists p} \ accepts \ (\mathbb{S}, r) \ iff \ \mathbb{D} \ accepts \ (\mathbb{S}[p \mapsto T], r) \ for \ some \ T \subseteq S.$$
(133)

12-6

Lectures on the modal  $\mu$ -calculus

**Proof.** Define the automaton  $\mathbb{D}^{\exists p} := \langle D, \Delta^{\exists p}, \Omega, d_I \rangle$ , with alphabet  $C = \wp(\mathsf{P})$ , by putting

$$\Delta^{\exists p}(a,c) := \Delta(a,c) \lor \Delta(a,c \cup \{p\}).$$

Clearly then  $\mathbb{D}^{\exists p}$  is a nondeterministic *MSO*-automaton, so it remains to prove that  $\mathbb{D}^{\exists p}$  satisfies (133). But since we may assume winning strategies to be functional, this proof is a variation on a proof given earlier, viz., that of Proposition 11.23. QED

But if *nondeterministic MSO*-automata admit existential second-order quantification, in order to transfer this closure property to the class of arbitrary automata, all we need is the following Simulation Theorem which states in particular that every *MSO*-automaton has a nondeterministic equivalent.

**Theorem 12.16 (Simulation Theorem)** There are effective constructions transforming an automaton of any of the kinds below to an equivalent automaton of any other kind:

1) Aut(1FOE),

- 2) Aut(Dis(BF(A))),
- 3) Aut(Dis(SBF(A))).

To prove the implication from 1) to 2) of this result, we need a model-theoretic result on monadic first-order logic, that will be of use later on as well.

**Proposition 12.17** There is an effective procedure transforming an arbitrary positive sentence in MFOE(A) to an equivalent disjunction of sentences in basic form.

The proof of this result, which we omit for the time being, is a fairly straightforward exercise in the theory of Ehrenfeucht-Fraïssé games.

**Proof of Theorem 12.16.** The implications from 3) to 2) and from 2) to 1) are trivial consequences of the definitions. The implication from 1) to 2) is immediate by Proposition 12.17.

The hardest part of the proof concerns the remaining implication, from 2) to 3). This, however, is an instance of the general simulation theorem that we proved in section 10.6. We only need to verify that the language Dis(SBF), seen as a one-step language, is  $\Lambda$ -distributive over Dis(BF), and therefore, over 1FOE, but we leave this as an exercise for the reader. QED

With this Simulation Theorem we have all the results that are needed for the inductive translation of second-order formulas to MSD-automata.

**Proof of Proposition 12.10.** As mentioned, the proposition is proved by induction on the complexity of  $\varphi \in MSO$ . The atomic case of the induction is covered by Proposition 12.11. For the induction step, the case where  $\varphi = \exists p.\psi$  is taken care of by Theorem 12.16 and Corollary 12.15. The remaining cases, where respectively  $\varphi = \neg \psi$  and  $\varphi = \varphi_0 \lor \varphi_1$ , are left as exercises for the reader. QED

Proposition 12.10 takes care of one direction of Theorem 12.9; for the opposite direction we need to find an equivalent formula  $\xi_{\mathbb{A}} \in MSO$  for each MSO-automaton  $\mathbb{A}$ .

**Proposition 12.18** There is an effective procedure transforming an MSO-automaton  $\mathbb{A}$  into a formula  $\xi_{\mathbb{A}} \in MSO^2(\mathsf{P})$  that is equivalent to  $\varphi$  over the class of tree models. That is:

$$\mathbb{A} \ accepts \ (\mathbb{S}, r) \ iff \ \mathbb{S}, r \models \xi_{\mathbb{A}}.$$

$$(134)$$

for any tree model S with root r.

**Proof.** For the time being we confine ourselves to a proof sketch. The basic idea is to encode the operational semantics of an *MSO*-automaton in monadic second-order logic; this works for nondeterministic automata over tree models, since we can express the working of a functional strategy.

To give a bit more detail, fix an MSO-automaton  $\mathbb{A}$ . We first transform  $\mathbb{A}$  into an equivalent nondeterministic automaton  $\mathbb{D} = (D, \Theta, \Omega, d_I)$ ; this is possible by Theorem 12.16. It then suffices to write down a monadic second-order formula  $\xi(x)$  in  $MSO^2(x)$  such that, for an arbitrary tree model  $\mathbb{S}$  with root r:

 $\mathbb{S} \models \xi[r]$  iff  $\exists$  has a functional positional winning strategy in  $\mathcal{A}(\mathbb{A}, \mathbb{S})@(a_I, r)$ .

Let S = (S, R, V) be a an arbitrary tree model with root r and let  $D = \{a_1, \ldots, a_n\}$ . Here we think of the  $a_i$  as second-order variables that will be quantified over existentially, in order to express the *existence* of a functional positional strategy. Take an arbitrary valuation  $U: D \to \wp(S)$ . It is easy to write down an  $MSO^2(x)$ -formula  $\varphi(\overline{a}, x)$  which holds of the resulting model  $S \oplus U$  iff  $|U(a_i)| \leq 1$  for each i, so that we may think of the associated marking  $m_U$ as a potential functional strategy of  $\exists$  in the acceptance game  $\mathcal{A}(\mathbb{A}, \mathbb{S})$ . Writing  $a_s$  for the unique state such that  $a_s \in m_U$ , we may then use the one-step formula  $\Theta(a, \sigma_V(s))$  as a basis for a first-order formula which expresses that this potential strategy induced by U actually provides a legitimate move for  $\exists$  at position  $(a_s, s)$ . Finally, note that any infinite match of  $\mathcal{A}(\mathbb{A}, \mathbb{S})@(a_I, r)$  corresponds to a branch of  $\mathbb{S}$  (that is, an infinite path starting at r); using a second-order variable b to range over such branches, it is then fairly straightforward to write down a formula stating that the highest parity occurring infinitely often on any match of an  $m_U$ -guided match is even. QED

## 12.3 Expressive completeness modulo bisimilarity

A central result in the theory of basic modal logic states that modal logic corresponds to the bisimulation invariant fragment of first-order logic. In this section we will prove an extension of this result stating that the modal  $\mu$ -calculus is the bisimulation invariant fragment of monadic *second-order* logic. While it is not difficult to show that every  $\mu$ ML-formula is equivalent to a bisimulation-invariant formula in MSO, it is the converse correspondence where the true importance of the result lies. We may see it as an expressive completeness result, stating that the modal  $\mu$ -calculus is sufficiently strong to express *every* bisimulation-invariant formula in monadic second-order logic. Note that in a context such as process theory, where we consider bisimilar pointed Kripke models as different representations of the *same* process, bisimulation-invariant properties are in fact the *only* relevant ones. In such a situation, we may read the bisimulation-invariance result as saying that modal fixpoint logic has the same expressive power as monadic second-order logic, when it comes to expressing relevant properties.

Lectures on the modal  $\mu$ -calculus

- ▶ Add examples of what can be expressed in MSO, and not in  $\mu$ ML:
  - every point has exactly two d-successors
  - the actual state does not lie on a cycle

We first show that there is truth-preserving translation mapping every formula of the modal  $\mu$ -calculus to an equivalent monadic second-order formula. Recall from Remark 12.4 that  $MSO_D^2(x, \mathsf{P})$  is the standard (two-sorted) version of monadic second-order logic.

**Definition 12.19** For any individual variable x we define, by induction on the complexity of a formula  $\varphi \in \mu ML_D$ , a translation  $ST_x : \mu ML_D(\mathsf{P}) \to \mathsf{MSO}^2_D(x, \mathsf{P})$ .

where  $\text{PRE}(\varphi, q)$  abbreviates the formula  $\forall y.(\text{ST}_y(\varphi)[q/p] \to q(y)).$ 

**Theorem 12.20** For any formula  $\varphi \in \mu ML$  we have  $\varphi \equiv ST_x(\varphi)$ , in the sense that

$$\mathbb{S}, s \Vdash \varphi \ iff \mathbb{S} \models \mathsf{ST}_x(\varphi)[s]$$

for every pointed Kripke model (S, s).

**Proof.** The proof of this theorem can be proved by a straightforward induction on the complexity of  $\mu$ ML-formulas.

For the inductive clause of the least fixpoint operator  $\mu$ , consider the formula  $\mu x.\varphi$ . We leave it for the reader to verify (using the inductive hypothesis) that the formula  $\text{PRE}(\varphi, q)$ expresses that q is a pre-fixpoint of  $\varphi$ , and that the formula  $\forall y.(p(y) \leftrightarrow \forall q.(\text{PRE}(\varphi, q) \rightarrow q(y)))$ expresses that p is the intersection of all pre-fixpoints of  $\varphi$ . QED

In the other direction, the actual result that we will prove is somewhat stronger than mere expressive completeness.

**Theorem 12.21** There is an effectively defined translation  $(\cdot)^*$ : MSO  $\rightarrow \mu$ ML such that a formula  $\varphi \in$  MSO is invariant under bisimulations iff it is equivalent to  $\varphi^*$ .

We will prove this result by automata-theoretic means. Recall that in the previous section we obtained the following characterisations of the languages MSO and  $\mu$ ML:

$$\begin{array}{rcl} \text{MSO} & \sim & Aut(\texttt{1FOE}) & (\text{on trees}) \\ \mu \texttt{ML} & \sim & Aut(\texttt{1FO}). \end{array}$$

The translation  $(\cdot)^*$ : MSO  $\rightarrow \mu$ ML mentioned in Theorem 12.21 will be based on a construction transforming 1FOE-automata into 1FO-automata, whereas this construction in its turn is based on a translation  $(\cdot)^*$  at the one-step level. For the details, we need to develop some

rudimentary model theory at the level of monadic first-order logic, in this case linking the one-step languages MFOE and MFO.

Recall from Definition 10.26 that 1FOE(A) and 1FO(A) denote the sets of A-positive sentence in the languages MFOE(A) and MFO(A) of monadic first-order logic with and without identity, respectively. Our translation  $(\cdot)^*$  involves the *basic forms* of Definition 12.13. Based on Proposition 12.17, we can provide the required translation from 1FOE to 1FO.

**Definition 12.22** Fix a set A of propositional variables. For an arbitrary sentence  $\chi^{=}(\overline{B}, \overline{C}) \in BF(A)$  we define

$$\left(\chi^{=}(\overline{B},\overline{C})\right)^* := \chi(\overline{B},\overline{C}),$$

and we extend this translation to the set Dis(BF(A)), simply by putting

$$(\bigvee_i \alpha_i)^* := \bigvee_i \alpha_i^*.$$

By Proposition 12.17 we may extend this definition to a map  $(\cdot)^* : 1FOE(A) \to 1FO(A)$ .

Observe that the translation is in fact very simple: we obtain  $(\chi^{=}(\overline{B}, \overline{C}))^*$  from  $\chi^{=}(\overline{B}, \overline{C})$  simply by forgetting about the identity formulas occurring in the latter formula.

To exhibit the model-theoretic relation between the formulas  $\alpha$  and  $\alpha^*$ , we need one further definition.

**Definition 12.23** Let  $f : D' \to D$  be a surjective map from one set D' to another set D, and let A be some set of variables. Given a valuation  $V : A \to \wp D$ , we define the valuation  $V_f : A \to \wp D'$ , by putting, for  $a \in A$ :

$$V_f(a) := \{ s' \in D' \mid f(s') \in V(a) \},\$$

and, conversely, given a valuation  $U: A \to \wp D'$ , we let

$$U^{f}(a) := \{ fs' \in D \mid s' \in U(a) \}$$

define a valuation on D.

The only fact that we need about these translations and valuations is the following Proposition. We will use this result to transform the winning strategy of  $\exists$  in one acceptance game to a winning strategy for her in a related acceptance game.

**Proposition 12.24** Let  $\alpha \in 1FOE(A)$  be some one-step formula, and let D be some set. We let  $\pi$  denote the left projection map  $\pi : D \times \omega \to D$ . 1) For any A-valuation V on D we have

$$D, V \models \alpha^* \text{ iff } D \times \omega, V_\pi \models \alpha.$$
(135)

2) As a corollary, for any A-valuation U on  $D \times \omega$  we have

$$D \times \omega, U \models \alpha \text{ only if } D, U^{\pi} \models \alpha^*$$

**Proof.** We leave the case where D is the empty set as an exercise for the reader, and focus on the case where  $D \neq \emptyset$ .

For part 1) of the Proposition, let  $\alpha$ , D and  $\pi$  be as in its formulation. We will prove the equivalence (135).

For the left-to-right direction of (135), assume that  $\langle D, V \rangle \models \chi(\overline{B}, \overline{C})$ . Let  $d_1, \ldots, d_n$ be elements in D satisfying the existential part of  $\chi(\overline{B}, \overline{C})$ , that is, for each i we find  $d_i \in \bigcap_{b \in B_i} V(b)$ . From the universal part of the formula it follows that for each  $d \in D$  there is a subset  $C_d \subseteq A$  such that  $d \in \bigcap_{c \in C_d} V(c)$ . Now we move to  $D \times \omega$ ; it is easy to see that its elements  $(d_1, 1), \ldots, (d_n, n)$  provide a sequence of n distinct elements that satisfy  $(d_i, i) \in \bigcap_{b \in B_i} V_{\pi}(b)$  for each i. In addition, every element (d, n) distinct from the ones in the mentioned tuple will satisfy  $(d, n) \in \bigcap_{c \in C_d} V_{\pi}(c)$ . From these observations it is immediate that  $\langle D \times \omega, V_{\pi} \rangle \models \chi^{=}(\overline{B}, \overline{C})$ .

For the opposite direction of (135), assume that  $\langle D \times \omega, V_{\pi} \rangle \models \chi^{=}(\overline{B}, \overline{C})$ . Let  $(d_1, k_1), \ldots, (d_n, k_n)$  be the sequence of distinct elements of  $D \times \omega$  witnessing the existential part of  $\chi^{=}(\overline{B}, \overline{C})$  in  $\mathbb{D}'$ . Then clearly,  $d_1, \ldots, d_n$  witness the existential part of  $\chi(\overline{B}, \overline{C})$  in  $\langle D, V \rangle$ . In order to show that  $\langle D, V \rangle$  also satisfies the universal part  $\forall z \bigvee_j \tau_{C_j}(z)$  of  $\chi$ , consider an arbitrary element  $d \in D$ . Take any  $m \in \omega \setminus \{k_1, \ldots, k_n\}$ , then (d, m) is distinct from each  $(d_i, k_i)$ . It follows that for some j we have  $(d, m) \in \bigcap_{c \in C_j} V_{\pi}(c)$ , and so we obtain  $d \in \bigcap_{c \in C_j} V(c)$ . Since d was arbitrary this shows that indeed  $\langle D, V \rangle \models \forall z \bigvee_j \tau_{C_j}(z)$ . So we have proved that  $\langle D, V \rangle \models \chi(\overline{B}, \overline{C})$ .

For part 2), assume that  $D \times \omega, U \models \alpha^*$ . It is straightforward to verify that  $U(a) \subseteq (U^{\pi})_{\pi}(a)$ , for all  $a \in A$ . Hence by monotonicity of  $\alpha$  with respect to the proposition letters in A, it follows that  $D \times \omega, (U^{\pi})_{\pi} \models \alpha^*$ . But then we find  $D, U^{\pi} \models \alpha^*$  by part 1) of the proposition. QED

#### Automata

Any translation between one-step formulas naturally induces a transformation of automata. In the current setting we obtain the following.

**Definition 12.25** Given an automaton  $\mathbb{A} = \langle A, \Theta, \Omega, a_I \rangle$  in Aut(1FOE), we define the map  $\Theta^* : (A \times \wp(\mathsf{P})) \to 1FO(A)$  by putting

$$\Theta^*(a) := (\Theta(a))^*,$$

and we let  $\mathbb{A}^*$  denote the automaton  $\mathbb{A}^* := \langle A, \Theta^*, \Omega, a_I \rangle$ .

We have now arrived at the main technical result of this section. It involves the notion of the  $\omega$ -unravelling  $\mathbb{E}_{\omega}(\mathbb{S}, s)$  of a model  $\mathbb{S}$  around a point s. This construction<sup>11</sup> generalizes that of the unravelling of a model (Definition 1.23).

**Definition 12.26** Let  $\kappa$  be a countable cardinal with  $1 \le \kappa \le \omega$ , and let  $(\mathbb{S}, s)$  be a pointed Kripke model of type (P, D). A  $\kappa$ -path through  $\mathbb{S}$  is a finite (non-empty) sequence of the form

<sup>&</sup>lt;sup>11</sup>In a later version of the notes, this construction will be defined in Chapter 1.

12 - 12

 $s_0d_1k_1s_1\cdots s_{n-1}d_nk_ns_n$ , where  $s_i \in S$ ,  $d_i \in \mathsf{D}$  and  $k_i < \kappa$  for each i, and such that  $R_{d_{i+1}}s_is_{i+1}$  for each i < n. The set of such paths is denoted as  $Paths^{\kappa}(\mathbb{S})$ ; we use the notation  $Paths_s^{\kappa}(\mathbb{S})$  for the set of paths starting at s. Given such a sequence  $\rho$ , we let  $\mathsf{last}(\rho) \in S$  denote its last item.

The  $\kappa$ -expansion of  $\mathbb{S}$  around s is the transition system  $\mathbb{E}_{\kappa}(\mathbb{S},s) = \langle Paths_{s}^{\kappa}(\mathbb{S}), \sigma^{\kappa} \rangle$ , where

$$\begin{split} &\sigma_V^{\kappa}(s_0 \cdots d_n k_n s_n) &:= \sigma_V(s_n), \\ &\sigma_d^{\kappa}(s_0 \cdots d_n k_n s_n) &:= \{(s_0 \cdots d_n k_n s_n dkt) \in Paths_s(\mathbb{S}) \mid R_d s_n t, 0 < k < \kappa\}. \end{split}$$

defines the coalgebra map  $\sigma^{\kappa} = (\sigma_V, (\sigma_d \mid d \in \mathsf{D})).$ 

It is not hard to check that the *unravelling* of a model (Definition 1.23) can be identified with its 1-expansion. It is straightforward to verify the following proposition.

**Proposition 12.27** For any countable cardinal  $\kappa$  with  $1 \leq \kappa \leq \omega$ , the function last, mapping a sequence to its last item, is a surjective bounded morphism from  $\mathbb{E}_{\kappa}(\mathbb{S}, s)$  to  $\mathbb{S}$  mapping the single-item sequence s to its single state s.

**Proposition 12.28** Let  $\mathbb{A}$  be an automaton in Aut(1FOE), then for any pointed Kripke model  $(\mathbb{S}, s)$  we have that

$$\mathbb{S}, s \Vdash \mathbb{A}^* \quad iff \ \mathbb{E}_{\omega}(\mathbb{S}, s), s \Vdash \mathbb{A}.$$
(136)

**Proof.** Let  $\mathbb{A} = \langle A, \Theta, \Omega, a_I \rangle$  and  $(\mathbb{S}, s)$  be as in the formulation of the Theorem. Let f denote the (surjective) bounded morphism from  $\mathbb{E}_{\omega}(\mathbb{S}, s)$  to  $\mathbb{S}$ , and recall that by definition f is the function last mapping an  $\omega$ -path to its final element. We will only prove the right-to-left direction of (136), leaving the (slightly easier) opposite direction as an exercise to the reader.

So assume that  $\mathbb{E}_{\omega}(\mathbb{S}, s), s \Vdash \mathbb{A}$ . Then  $\exists$  has a (positional) winning strategy h in the acceptance game  $\mathcal{A}^{\omega} := \mathcal{A}(\mathbb{A}, \mathbb{E}_{\omega}(\mathbb{S}, s))@(a_0, s_0)$ , where we write  $a_0 := a_I$  and  $s_0 := s$ . We need to provide her with a winning strategy h' in the acceptance game  $\mathcal{A} := \mathcal{A}(\mathbb{A}^*, \mathbb{S})@(a_0, s_0)$ , and we will define h' by induction on the length of a partial  $\mathcal{A}$ -match  $\Sigma = (a_i, s_i)_{0 \leq i \leq n}$ . Via a simultaneous induction we define a partial  $\mathcal{A}^{\omega}$ -match  $\Sigma' = (a_i, s'_i)_{0 \leq i \leq n}$  which will be guided by  $\exists$ 's winning strategy h and satisfies  $f(s'_i) = s_i$ , for all i.

For the inductive step of these definitions, consider a partial  $\mathcal{A}$ -match  $\Sigma = (a_i, s_i)_{0 \leq i \leq n}$ . Without loss of generality we may assume that  $\Sigma$  itself is guided by h', and inductively we may assume the existence of an h-guided shadow match  $\Sigma' = (a_i, s'_i)_{0 \leq i \leq n}$  of  $\mathcal{A}^{\omega}$  such that  $f(s'_i) = s_i$ , for all i. In order to extend the definition of h', so that it defines a move for  $\exists$  in the partial match  $\Sigma$ , obviously we consider this partial shadow match. Let  $U : A \to \wp \sigma_R^{\omega}(s')$ be the A-valuation picked by  $\exists$ 's winning strategy h in the match  $\Sigma'$ . If we compare the collections  $\sigma_R(s)$  and  $\sigma_R^{\omega}(s')$  of successors of s and s' respectively, it is obvious that f restricts to a surjection from  $\sigma_R^{\omega}(s')$  to  $\sigma_R(s)$ . Hence we may take the valuation

$$U^f: A \to \wp \sigma_R(s),$$

induced by U as in Definition 12.23, as the move given by the strategy h in the partial match  $\Sigma$ .

To see that this move is legitimate, we need to show that

$$\sigma_R, U^f \models \Theta^*(a_n, \sigma_V(s_n)), \tag{137}$$

that is, the one-step formula  $\Theta^*(a_n, \sigma_V(s_n))$  holds in the A-structure  $(\sigma_R, U^f)$ . It will be convenient to think of  $\sigma_R^{\omega}(s')$  as the set  $\sigma_R(s) \times \omega$ , and of f as the projection map  $\pi$ :  $\sigma_R(s) \times \omega \to \sigma_R(s)$ . Then (137) is immediate by Proposition 12.242) and the fact that

$$\sigma_R^{\omega}, U \models \Theta(a_n, \sigma_V(s_n)), \tag{138}$$

simply because the valuation U is the legitimate move provided by  $\exists$ 's winning strategy h. Clearly then, the valuation  $U^f$  is a legitimate move for  $\exists$ .

In order to finish the inductive definition, we need to show how to extend, for any response (b,t) of  $\forall$  to  $\exists$ 's move  $U^f$ , the shadow match  $\Sigma'$  with a position (b,t') such that ft' = t. But this is straightforward: if (b,t) is a legitimate move for  $\forall$  in  $\mathcal{A}$  at position U, then we have  $t \in U^f(b)$ , and so by definition there is a state  $t' \in \sigma_R^{\omega}(s')$  such that ft' = t and  $t' \in U(b)$ . Clearly then the continuation  $\Sigma' \cdot (b,t')$  of  $\Sigma'$  satisfies the requirements.

We will now show that the just defined strategy h' is in fact winning for  $\exists$  in  $\mathcal{A}$ . For this purpose, consider a full  $\mathcal{A}$ -match  $\Sigma$  which is guided by h'.

First consider the case where  $\Sigma$  is finite. It is not hard to prove, using the existence of the *h*-guided shadow match  $\Sigma'$ , that the player who got stuck in  $\Sigma$  is  $\forall$ .

Having taken care of the finite matches, we now consider the case where  $\Sigma = (a_i, s_i)_{0 \leq i < \omega}$ is infinite. It is not difficult to see that in this case there is an *h*-guided infinite shadow match  $\Sigma' = (a_i, s'_i)_{0 \leq i < \omega}$  of  $\mathcal{A}^{\omega}$ , such that  $fs'_i = s_i$  for all  $i < \omega$ . But since *h* was assumed to be a winning strategy for  $\exists$  in  $\mathcal{A}^{\omega}$ ,  $\Sigma'$  is actually won by her. But since the priority maps of  $\mathbb{A}$  and  $\mathbb{A}^*$  are exactly the same, from this it is immediate that  $\exists$  is also the winner the  $\mathcal{A}$ -match  $\Sigma$ . QED

### Proof of main result

As we shall see now, the expressive completeness of the modal  $\mu$ -calculus is an almost immediate corollary of Proposition 12.28, given our earlier automata-theoretic characterizations of MSO and the modal  $\mu$ -calculus.

**Proof of Theorem 12.21.** Let  $\varphi \in MSO$  be a monadic second-order formula, and let  $\mathbb{B}_{\varphi} \in Aut(1FOE)$  be the automaton as given in Theorem 12.9. Then by Theorem 12.8 there is a formula  $\varphi^* \in \mu ML$  that is equivalent to the translation  $(\mathbb{B}_{\varphi})^*$  of  $\mathbb{B}_{\varphi}$ . Clearly then  $\varphi^*$  has been effectively obtained from  $\varphi$ .

We will show that  $\varphi$  is invariant under bisimulations iff it is equivalent to the formula  $\varphi^*$ . The direction from right to left is immediate since formulas of the modal  $\mu$ -calculus are bisimulation invariant.

For the opposite direction, observe that by Proposition 12.28 and the definition on  $\varphi^*$ , for an arbitrary pointed Kripke model ( $\mathbb{S}, s$ ) we have

$$\mathbb{S}, s \Vdash \varphi^* \text{ iff } \mathbb{E}_{\omega}(\mathbb{S}, s), s \Vdash \varphi.$$
(139)

Now assume that  $\varphi$  is bisimulation invariant, then we have that

$$\mathbb{S}, s \Vdash \varphi \text{ iff } \mathbb{E}_{\omega}(\mathbb{S}, s), s \Vdash \varphi.$$

$$(140)$$

Combining these two observations, we see that  $\mathbb{S}, s \Vdash \varphi^*$  iff  $\mathbb{S}, s \Vdash \varphi$ . But since  $(\mathbb{S}, s)$  was arbitrary, this means that  $\varphi$  and  $\varphi^*$  are equivalent, as required. QED

## Notes

The result that the modal  $\mu$ -calculus is the bisimulation-invariant fragment of monadic secondorder logic is due to Janin & Walukiewicz [8].

# Exercises

**Exercise 12.1** Let (D, V) and (D', V') be two one-step models over the same set A of monadic predicates. Then (D, V) is a quotient of (D', V') if there is a surjection  $f : D' \to D$  such that  $V' = V_f$ . An MFOE-sentence  $\alpha$  is invariant under taking quotients if we we have that  $(D, V) \models \alpha$  iff  $(D', V') \models \alpha$ , whenever (D, V) is a quotient of (D', V').

Let  $\alpha$  be an MFOE-sentence. Prove that  $\alpha$  is invariant under taking quotients iff  $\alpha \equiv \alpha^*$ . Conclude that 1FO is the 'quotient-invariant fragment' of 1FOE.

# A Mathematical preliminaries

Sets and functions We use standard notation for set-theoretic operations such as union, intersection, product, etc. The power set of a set S is denoted as  $\wp(S)$  or  $\wp S$ , and we sometimes denote the relative complement operation as  $\sim_S X := S \setminus X$ . The size or cardinality of a set S is denoted as |S|.

We write  $f: A \to B$  to denote that f is a (total) function from A to B, and  $f: A \stackrel{\circ}{\to} B$ in case f is partial. In the latter case we write  $f(a)\uparrow$  if f(a) is defined, and  $f(a)\downarrow$  if this is not the case. Given a set  $X \subseteq A$ , we let  $f[X] := \{f(a) \in B \mid a \in X\}$  denote the image of Xunder f, and given  $Y \subseteq B$ ,  $f^{-1}[Y] := \{a \in A \mid f(a) \in Y\}$  denotes the preimage of Y. In case f is a bijection, we let  $f^{-1}$  denote its inverse. The composition of two functions  $f: A \to B$ and  $g: B \to A$  is denoted as  $g \circ f$  or gf, and the set of functions from A to B will be denoted as either  $B^A$  or  $A \to B$ .

It is well-known that there is a bijective correspondence, often called 'currying':

$$(A \times B) \to C \cong A \to (B \to C),$$

which associates, with a function  $f : A \times B \to C$ , the map that, for each  $a \in A$ , yields the function  $f_a : B \to C$  given by  $f_a(b) := f(a, b)$ .

**Relations** Given a relation  $R \subseteq A \times B$ , we introduce the following notation. Dom(R) and Ran(R) denote the domain and range of R, respectively.  $R^{-1}$  denotes the converse of R. For  $R \subseteq S \times S$ ,  $R^*$  denotes the reflexive-transitive closure of R, and  $R^+$  the transitive closure. For  $X \subseteq A$ , we put  $R[X] := \{b \in B \mid (a, b) \in R \text{ for some } a \in X\}$ ; in case  $X = \{s\}$  is a singleton, we write R[s] instead of  $R[\{s\}]$ . For  $Y \subseteq B$ , we will write  $\langle R \rangle Y$  rather than  $R^{-1}[Y]$ , while [R]Y denotes the set  $\{a \in A \mid b \in Y \text{ whenever } (a, b) \in R\}$ . Note that  $[R]Y = A \setminus \langle R \rangle (B \setminus Y)$ . A relation R on S is *acyclic* if there are no elements s such that  $R^+ss$ .

There are varous ways to lift a relation  $Z \subseteq A \times A'$  to a relation between  $\wp(A) \times \wp(A')$ :

 $\overrightarrow{\wp}(Z) := \{(B,B') \mid \text{ for all } b \in B \text{ there is a } b' \in B' \text{ such that } (b,b' \in Z\}$  $\overleftarrow{\wp}(Z) := \{(B,B') \mid \text{ for all } b' \in B' \text{ there is a } b \in B \text{ such that } (b,b' \in Z\}$  $\overrightarrow{\wp}(Z) := \overrightarrow{\wp}(Z) \cap \overleftarrow{\wp}(Z)$ 

Similarly, we lift  $Z \subseteq A \times B$  to  $\widetilde{Z} \subseteq A^{\omega} \times B^{\omega}$  given by

$$Z := \left\{ (a_i)_{0 \le i < \omega}, b_i \right\}_{0 \le i < \omega} \mid (a_i, b_i \in Z \text{ for all } i < \omega \right\}$$

An equivalence relation on a set A is a binary relation that is reflexive, symmetric and transitive. The equivalence class or cell of an element  $a \in A$  relative to an equivalence relation is the set of all elements in A that are linked to a by the relation.

A preorder is a structure  $(P, \sqsubseteq)$  such that  $\sqsubseteq$  is a reflexive and transitive relation on P; given such a relation we will write  $\sqsubset$  for the asymmetric version of  $\sqsubseteq$  (given by  $u \sqsubset v$  iff  $u \sqsubseteq v$ but not  $v \sqsubseteq u$ ) and  $\equiv$  for the equivalence relation induced by  $\sqsubseteq$  (given by  $u \equiv v$  iff  $u \sqsubseteq v$  and  $v \sqsubseteq u$ ). Cells (that is, equivalence classes) of such a relation will often be called *clusters*. A preorder is directed if for any two points u and v there is a w such that  $u \sqsubseteq w$  and  $v \sqsubseteq w$ . A *partial order* is a preorder  $\sqsubseteq$  which is antisymmetric, i.e., such that  $p \sqsubseteq q$  and  $q \sqsubseteq p$  imply p = q. Observe that in a poset we have that  $p \sqsubset q$  iff  $p \sqsubseteq q$  and  $p \neq q$ . Sequences, lists and streams Given a set C, we define  $C^*$  as the set of finite lists, words or sequences over C. We will write  $\varepsilon$  for the empty sequence, and define  $C^+ := C^* \setminus \{\varepsilon\}$ as the set of nonempty words. An infinite word, or stream over C is a map  $\gamma : \omega \to C$ mapping natural numbers to elements of C; the set of these maps is denoted by  $C^{\omega}$ . We write  $C^{\infty} := C^* \cup C^{\omega}$  for the set of all sequences over C. We sometimes write  $(a_n)_{0 \le i < n}$  to denote the finite word  $a_0a_1 \cdots a_n$ , and  $(a_i)_{0 \le i < \omega}$  for the stream  $a_0a_1a_2\cdots$ ; to cover both cases we may write  $(a_i)_{0 \le i < \kappa}$  with the understaning that  $\kappa \in \omega \cup \{\omega\}$ , that is,  $\kappa$  is either finite or equal to  $\omega$ .

The concatenation of a (finite) word u and a (finite or infinite) word v is denoted as  $u \cdot v$ or uv. Where  $\kappa \in \omega \cup \{\omega\}$ , and  $(\pi_i)_{0 \leq i < \kappa}$  is a sequence of finite sequences, we denote its concatenation as  $\bigcirc_{0 \leq i < \kappa} \pi_i$  (with the understanding that this denotes the empty sequence  $\varepsilon$ in case  $\kappa = 0$ ).

For a nonempty sequence  $\pi$ , first $(\pi)$  denotes the first element of  $\pi$ . In the case that  $\pi$  is finite and nonempty we write  $\mathsf{last}(\pi)$  for the last element of  $\pi$ . Given a stream  $\gamma = c_0 c_1 \ldots$  and two natural numbers i < j, we let  $\gamma[i, j)$  denote the finite word  $c_i c_{i+1} \ldots c_{j-1}$ .

Next to the concatenation operation we will occasionally need the *fusion* operation  $\diamond$ :  $(C^* \times C^{\infty}) \xrightarrow{\circ} (C^* \times C^{\infty})$ . The fusion  $u \diamond v$  of u and v is defined iff  $\mathsf{last}(u) = \mathsf{first}(v)$  (which presupposes that u and v are both non-empty) and in this case we set  $u \diamond v := u \cdot \mathsf{tail}(v)$ , where  $\mathsf{tail}(v)$  is the sequence we obtain from v by removing its first element.

We use  $\sqsubseteq$  for the initial segment relation between sequences, and  $\sqsubset$  for the proper (i.e., irreflexive) version of this relation. An sequence  $(\pi_i)_{0 \le i < \kappa}$  is *increasing* if i < j implies  $\pi_i \sqsubseteq \pi_j$ , and *stricty increasing* if i < j implies  $\pi_i \sqsubset \pi_j$ , for all  $i, j < \kappa$ . Given an infinite increasing sequence  $(\pi_n)_{0 \le n < \omega}$ , we define its *limit*  $\lim_{n \to \infty} ((\pi_i)_{0 \le i < \omega}) \in C^{\infty}$  as the sequence  $\pi$  given by

$$\pi(n) := \begin{cases} \pi_m(n) & \text{if } \pi_m(n) \downarrow \\ \uparrow & \text{if } \pi_m(n) \uparrow, \text{ for all } m < \omega, \end{cases}$$

where we leave it as an exercise for the reader to verify that this is well-defined. Given a word  $u \in C^*$  and a subset  $A \subseteq C$ , we define the *restriction*  $u \upharpoonright_A$  of u to A by the following induction:

$$\begin{aligned} \varepsilon \upharpoonright_A &:= \varepsilon \\ (uc) \upharpoonright_A &:= \begin{cases} u \upharpoonright_A c & \text{if } c \in A \\ u \upharpoonright_A & \text{if } c \notin A. \end{cases} \end{aligned}$$

This definition is extended to infinite sequences by putting  $\pi \upharpoonright_A := \lim_{n \to \infty} ((\pi_n) \upharpoonright_A)$ . Note that  $\pi \upharpoonright_A$  is not necessarily infinite.

**Graphs and trees** A (directed) graph is a pair  $\mathbb{G} = \langle G, E \rangle$  consisting of a set G of nodes or vertices and a binary edge relation E on G. A finite path through such a graph is a nonempty sequence  $(s_i)_{0 \le i \le n} = s_0 \cdots s_n$  in  $G^*$  such that  $Es_i s_{i+1}$  for all i < n. Similarly, an infinite path is a sequence  $(s_i)_{0 \le i \le \omega} = s_0 s_1 \cdots$  in  $G^{\omega}$  such that  $Es_i s_{i+1}$  for all  $i < \omega$ . A (proper) cycle is a path  $s_0 \cdots s_n$  such that n > 0,  $s_0 = s_n$  and  $s_0, \ldots, s_{n-1}$  are all distinct. A subset  $D \subseteq G$  is cycle-critical if it every cycle has a node in D. A graph is acyclic if it has no cycles; a dag is a directed, acyclic graph.

A tree is a graph  $\mathbb{T} = (T, R)$  which contains a node r, called a root of  $\mathbb{T}$ , such that every element  $t \in T$  is reachable by a unique path from r. (In particular, this means that  $\mathbb{T}$  is acyclic, and that the root is unique.) Where s and t are nodes in some tree (T, R), if  $(s,t) \in R$  we say that t is a child of s and that s is the parent of t. If  $(s,t) \in R^+$  we call s an ancestor of t, and t a descendant of s. Distinct nodes with the same parent are called siblings.

▶ define branches

Fact A.1 (König's Lemma) Let  $\mathbb{G}$  be a finitely branching, acyclic tree. If  $\mathbb{G}$  is infinite, then it has an infinite path.

**Order and lattices** A partial order is a structure  $\mathbb{P} = \langle P, \leq \rangle$  such that  $\leq$  is a reflexive, transitive and antisymmetric relation on P. Given a partial order  $\mathbb{P}$ , an element  $p \in P$  is an upper bound (lower bound, respectively) of a set  $X \subseteq P$  if  $p \geq x$  for all  $x \in X$  ( $p \leq x$  for all  $x \in X$ , respectively). If the set of upper bounds of X has a minimum, this element is called the *least upper bound*, supremum, or join of X, notation:  $\bigvee X$ . Dually, the greatest lower bound, infimum, or meet of X, if existing, is denoted as  $\bigwedge X$ . Generally, given a statement S about ordered sets, we obtain its dual statement by replacing each occurrence of  $\leq$  with  $\geq$  and vice versa. The following principle often reduces our work load by half;

# Order Duality Principle If a statement holds for all ordered sets, then so does its dual statement.

A partial order  $\mathbb{P}$  is called a *lattice* if every two-element subset of P has both an infimum and a supremum; in this case, the notation is as follows:  $p \wedge q := \bigwedge \{p, q\}, p \vee q := \bigvee \{p, q\}$ . Such a lattice is *bounded* if it has a minimum  $\bot$  and a maximum  $\top$ . A partial order  $\mathbb{P}$  is called a *complete lattice* if every subset of P has both an infimum and a supremum. In this case we abbreviate  $\bot := \bigvee \emptyset$  and  $\top := \bigwedge \emptyset$ ; these are the smallest and largest elements of  $\mathbb{C}$ , respectively. A complete lattice will usually be denoted as a structure  $\mathbb{C} = \langle C, \bigvee, \bigwedge \rangle$ . Key examples of complete lattices are full power set algebras: given a set S, it is easy to show that the structure  $\langle \wp(S), \bigcup, \bigcap \rangle$  is a complete lattice.

Given a family  $\{\mathbb{P}_i \mid i \in I\}$  of partial orders, we define the *product* order  $\prod_{i \in I} \mathbb{P}_i$  as the structure  $\langle \prod_{i \in I} P_i, \leq \rangle$  where  $\prod_{i \in I} P_i$  denotes the cartesian product of the family  $\{P_i \mid i \in I\}$ , and  $\leq$  is given by  $\pi \leq \pi'$  iff  $\pi(i) \leq_i \pi'(i)$  for all  $i \in I$ . It is not difficult to see that the product of a family of (complete) lattices is again a (complete) lattice, with meets and joins given coordinatewise. For instance, given a family  $\{\mathbb{C}_i \mid i \in I\}$  of complete lattices, and a subset  $\Gamma \subseteq \prod_{i \in I} C_i$ , it is easy to see that  $\Gamma$  has a least upper bound  $\bigvee \Gamma$  given by

$$\big(\bigvee \Gamma\big)(i) = \bigvee \{\gamma(i) \mid \gamma \in \Gamma\},$$

where the join on the right hand side is taken in  $\mathbb{C}_i$ .

**Ordinals** A set S is *transitive* if  $S \subseteq \wp(S)$ ; that is, if every element of S is a subset of S, or, equivalently, if  $S'' \in S' \in S$  implies that  $S'' \in S$ . An *ordinal* is a transitive set of which all elements are also transitive. From this definition it immediately follows that any element of an ordinal is again an ordinal. We let  $\mathcal{O}$  denote the class of all ordinals, and use lower case Greek symbols  $(\alpha, \beta, \gamma, \ldots, \lambda, \ldots)$  to refer to individual ordinals.

The smallest, *finite*, ordinals are

We will also refer to the finite ordinals as *natural numbers*; where  $m \le n$ , we define  $[m, n] := \{\ell \mid m \le \ell \le n\}$ , and  $[m, n) := \{\ell \mid m \le \ell < n\}$ .

In general, the successor  $\alpha + 1$  of an ordinal  $\alpha$  is the set  $\alpha \cup {\alpha}$ ; it is easy to check that  $\alpha + 1$  is again an ordinal. Ordinals that are not the successor of an ordinal are called *limit* ordinals. Thus the smallest limit ordinal is 0; the next one is the first infinite ordinal

$$\omega := \{0, 1, 2, 3, \ldots\}.$$

But it does not stop here: the successor of  $\omega$  is the ordinal  $\omega + 1$ , etc. It is important to realize that there are in fact too many ordinals to form a set:  $\mathcal{O}$  is a proper class. As a consequence, whenever we are dealing with a function  $f : \mathcal{O} \to A$  from  $\mathcal{O}$  into some set A, we can conclude that there exist distinct ordinals  $\alpha \neq \beta$  with  $f(\alpha) = f(\beta)$ . (Such a function f will also be a class, not a set.)

We define an ordering relation < on ordinals by:

$$\alpha < \beta$$
 if  $\alpha \in \beta$ .

From this definition it follows that  $\alpha = \{\beta \text{ in } \mathcal{O} \mid \beta < \alpha\}$  for every ordinal  $\alpha$ . The relation < is obviously transitive (if we permit ourselves to apply such notions to relations that are classes, not sets). It follows from the axioms of ZFC that < is in fact *linear* (that is, for any two ordinals  $\alpha$  and  $\beta$ , either  $\alpha < \beta$ , or  $\alpha = \beta$ , or  $\beta < \alpha$ ) and *well-founded* (that is, every non-empty set of ordinals has a smallest element).

The fact that < is well-founded allows us to generalize the principle of induction on the natural numbers to the transfinite case.

Transfinite Induction Principle In order to prove that all ordinals have a certain property, it suffices to show that the property is true of an arbitrary ordinal  $\alpha$  whenever it is true of all ordinals  $\beta < \alpha$ .

A proof by transfinite induction typically contains two cases: one for successor ordinals and one for limit ordinals (the base case of the induction is then a special case of a limit ordinal). Analogous to the transfinite inductive proof principle there is a *Transfinite Recursion Principle* according to which we can construct an ordinal-indexed sequence of objects.
